PERFORATING TYPHOID ULCER—PERITONITIS—OPERATION—RECOVERY.

BY ROBERT ABBE, M.D.,

NEW YORK.

LATE on Saturday afternoon, November 3d, I was asked by Dr. J. H. Bache, of this city, to see with him a young married woman, twenty-one years of age, whom he had been attending with typhoid fever for three weeks. Every characteristic symptom had been present: rather free diarrhœa, evening temperature ranging about 102° F., and delirium every night during the second week. On Monday, October 29th, the patient seemed to be beginning convalescence, all the symptoms abating. Wednesday night she was seized with great pain, as if something had suddenly given way in her abdomen below her navel. She vomited, and was much collapsed. Her temperature rose promptly to 102° F., with great pain and tympanites.

Dr. Bache at once suspected perforation, kept the patient absolutely quiet, and treated her by poultices over the abdomen, and enough morphine to allay her great pain. The temperature fell somewhat, but for two days varied from 102° to 102½° F. Her vomiting was less, but her tympanites continued. At the end of the second day her condition became suddenly worse: the pulse became weaker; the abdomen greatly distended, with skin stretched and shining.

As she had survived two and a half days, Dr. Bache thought, despite her low state, surgery might help her. On examination I found her with mind clear, but heart and respiration oppressed by her distended state; tongue dry and moderately coated; pulse, 140; temperature, 104° F. The distended abdomen was dull in the hypogastrium half-way to the navel, and the dulness extended along the right Poupart ligament. I confirmed the diagnosis and advised the earliest possible operation.

The patient was in too low a state to be removed to a hospital, so the most complete arrangements possible were made to do a thorough operation at the house. In this I was assisted by Drs. A. L. Fisk and Nelson H. Henry, of Trinity Hospital.

A median incision below the navel exposed distended coils of deeply congested and greatly inflamed intestine, smeared with sticky lymph. The pelvis and lower abdomen were filled with a collection of foul, purulent, and fetid intestinal extravasation. This was feebly confined by matted coils of intestines, loosely glued together, that broke apart on being touched, but which, being recognized, enabled me to introduce clean laparotomy sponges under the upper abdominal wall, where a few coils were seen which showed more recent inflammation. Two pints of foul, purulent fluid and thick lymph were cleaned out, and the abdomen irrigated with warm and weak sublimate solution, 1 to 20,000, followed by plain warm-water irrigation.

Search now revealed the cause. The lower part of the ileum showed many thick oval patches in its wall—their long axes parallel to that of the gut, and easily identified by touch as the gut was passed through the fingers, and shown also by increased subperitoneal hyperæmia. One such inflamed Peyer's patch showed a gangrenous perforation a quarter of an inch in diameter, from which intestinal contents were seen to pump out. This was promptly closed by interrupted silk sutures, over which two layers of Halsted mattress stitches were placed, these being found to be the only suture that would hold in the tender and inflamed intestinal coat. A large abdominal tamponade of iodoform gauze was placed within the abdomen and pelvis, and no attempt made to close the wound. A hot black coffee and whiskey enema assisted greatly in preventing shock; the patient was put back to bed in three-quarters of an hour from the beginning of etherization.

She passed a good night and had a stronger pulse next morning. Pulse, 132; temperature, 102½° F.; tympanites less. At the end of forty-eight hours after operation, as she was in good condition, except for tympanites, I removed the tamponade; reapplied a loose one, and gave five grains of calomel. This produced numerous loose movements and she felt much better. Temperature, 101½° F.; pulse, 120. A little fluid fæces leaked from the wound after the calomel action, showing that the perforation had slightly opened. This continued for two weeks, when it ceased, and the abdominal wound pursued the usual course, closing in rapidly by granulations, and has left a narrow and firm scar.

After the third day her appetite improved and a rapid convalescence ensued.

Remarks.—The recording of this one case is not an occasion for a long paper on the subject, which would be superfluous in view of the three excellent ones by Mears,[1] Fitz,[2] and Van Hook,[3] written in 1888 and 1891. But it is an opportunity to express a surgical view of the subject more mature than would have been possible a few years since. For, while but few cases of this emergency have as yet been operated on, corresponding conditions of perforating gastric, duodenal, and appendical ulcers have been relatively common in the hands of the general surgeon. Excepting for the exhausted condition of the patient during typhoid fever, there is practically no difference, as far as I can discern, between the conduct of perforations in various parts of the alimentary tract. The same sudden onset of symptoms is witnessed, acute tearing pain, shock, vomiting followed by tympany and peritonitis. The same sequel pertains as to the peritoneal exudation. In one case, shock or non-reparative inflammation will succeed and be fatal before operation, or in spite of operation; in another, a fine quality of plastic lymph will repair the damaged part, or hold the extravasation in check until the surgeon can operate. No doubts exist in my own mind that recovery without operation can follow perforation anywhere—and in typhoid also. But this is certainly infinitely rarer here than in other diseases, because the parts are centrally located where the explosion occurs and a natural outlet through the abdominal wall does not easily take place. The case narrated later, where a typhoid ulcer perforated and a resulting abscess was opened in the perineum, is consistent with much of nature's good work.

[1] J. Ewing Mears: Transactions of the American Surgical Association, 1888.

[2] Fitz: Transactions of the Association of American Physicians, 1891, vol. vi., p. 200.

[3] Philadelphia Medical News, 1891, vol. ix. p. 591. Chicago Medical Record, 1891, vol. ii., pp. 229-270.

Fitz says: "The similarity of the symptoms of typhoid perforations of the bowel and those of the appendix, is striking. Cases of perforating appendix have repeatedly been regarded as typhoid fever, and, as a rule, the symptoms of typhoid which suggest perforation of the bowels are those which in the absence of typhoid would be regarded as diagnostic of appendicitis. The symptoms are not merely similar, they are actually identical. Even to the usual localization of the consequent peritonitis to the right iliac fossa."

This lucid statement by Fitz must appeal to every observer of appendicitis cases, as true to the letter. Why one class of cases should be left to die, while we operate on all appendicitis cases when perforation can be recognized, does not appear. The typhoid statistics are improving, and as it was in the other, we may here also soon record as much gain in the near future.

Van Hook operated on a desperate case at two o'clock in the afternoon, where perforation had taken place at 5 A.M. The extravasation was wide of the ulcer. The patient was washed out with plain boiled water, sewed up tight, rescued from collapse, and saved.

Now, we have not yet learned enough about the surgical procedure to do exactly right in all cases, and it gives me some satisfaction to state in a few words what I regard of growing importance in the work. The technical points are known to every surgeon, but very essential do I consider it, that the surgeon should never be so hasty in getting at his work that he enters upon it handicapped by poor assistance, poor light, poor arrangements for irrigation and sponging, or inadequate plans for restoration from shock.

I regard the rescue of these cases from collapse as most important. I always give a restorative enema at the end of operation (often on the table) composed of a cup of hot black coffee and one or two ounces of whiskey, followed later by hypodermics of strychnine and digitalis, abundant heat about the body, and elevation of the foot of the bed for twelve hours. Very warm saline infusion into the vein, of at least one pint, must always be tried as a valuable resort.

To quote from Dr. Van Hook's article, the statistics up to October, 1891, of operation for typhoid perforation were:

"1884. Mikulicz, four cases, one recovery, though, unfortunately, the diagnosis is doubtful.
1885. Lücke, one case, resection, death.
1886. Escher, one case, recovery, but the case is regarded by Louis as one of appendicitis.
1886. Greig Smith, one case, doubtful diagnosis, death.
1886. Bartlett, one case, death.
1887. Bontecou, one case, death.
1887. Morton, one case, death.
1889. Bontecou, one case, death.
1889. Senn, volvulus and perforation, one case, death.
1889. Hahn, two cases, death.
1890. Kimura, one case, death.
1890. Taylor, one case, recovered.
1891. Van Hook, three cases, two dead, one recovered.

Making in all, nineteen laparotomies and four recoveries.

"Mikulicz's case was said by the author to be of doubtful origin. That of Escher was probably a perforative appendicitis. Taylor's case should not be counted, as it was operated on ten days after onset of symptoms, and is not demonstrated to have been typhoid perforation.

"If we include all the doubtful cases, the present recovery (Van Hook's case), as appears from the literature at command, is the nineteenth case and fourth recovery. If we include only closely diagnosticated cases, it is the twelfth case and first recovery."

In 1894, Cayley[1] and H. Allingham[2] each reported a fatal case after early operation, stitching the gut to the abdominal wound.

In *The Lancet*, 1894, vol. i., p. 1615, is recorded a case of supposed perforation with collapse and recovery, in a female, which I am strongly inclined to regard as one of high intestinal hemorrhage in the fourth week, indicated by a drop in temperature to 95°, rapid thready pulse, cold extremities and extreme pallor, and fulness of the umbilical region and tenderness in the right hypochondrium. No pain existed and the patient made a slow recovery with a very thin pulse. No operation was performed.

In August, 1893, Dr. Newton, of Chicago,[1] treated a case of supposed perforation by morphine; as the parents objected to the operation. The case seems undoubted, and the boy recovered, an abscess of the pelvis being opened a fortnight later in the perineum.

Netschagaw, of St. Petersburg, records a case this year of resection of a portion of perforated bowel in typhoid, with recovery.

Since Van Hook's successful case in 1891, there have been reported the following operations:

1894. Cayley and Bland Sutton, one case, fatal.
1894. H. Allingham, one case, fatal.
1894. Netschagaw, Medical News, December 1. 1894, p. 609, one case, recovery.
1894. Abbe, one case, recovery.
1894. Alexandroff,[2] one case, death.

If we accept all the nineteen laparotomies for so-called typhoid perforations with four recoveries, collected by Van Hook, and add the five new ones, we have 24 cases and 6 recoveries.

If we throw out doubtful cases—which I agree with Van Hook should be done—and accept only 12 of the 19 with 1 recovery—to which the above five are added—then the correct statistics revised up to date, stand, 17 cases with 3 recoveries.

CASES OF PERFORATION OF THE STOMACH FROM ULCER, WITH SUCCESSFUL OPERATION.

By A. V. ATHERTON, M.D.,

SURGEON TO ST. JOHN'S HOSPITAL, TORONTO, CANADA.

Case I. February 5, 1884.—R. O'B——, aged about fifty, night watchman in gas-house. For three years has been much troubled by dyspepsia, giving rise to pain in the stomach, flatulence, and more or less vomiting. Fifteen months ago had a severe attack of hæmatomosis with melæna, and accompanied by syncope. For the three following months he suffered from great anæmia and general anasarca. After this length of time he began to resume his customary duties, but his old dyspepsia persisted.

One morning, after his usual night-watch, he was suddenly seized with a most excruciating pain in the epigastrium, causing him to drop on the floor where he stood. He also vomited, and great drops of sweat came out on his face. He was carried in the arms of his fellow-workmen to his home, which was close by.

I visited him about two hours afterward, and found him lying on his back with knees drawn up, complaining bitterly of pain in upper abdomen, increased by long breath or movement of body; countenance anxious; extremities and nose cold and clammy, and a feeble pulse of 60. He reported having eaten only a light lunch in the night, nothing since. He described the pain with which he was seized as feeling "just as if a spike were being driven through" him.

Vomiting of a little gruel-like fluid occurred during my visit.

I at once gave one-fourth of a grain of morphine hypodermically, and ordered the same dose *p. r. n.* by the mouth. To have only small bits of ice to quench thirst. Hot things to be applied to body till reaction occurred.

12 M.—Has had one dose of morphine since visit,

[1] Chicago Medical Recorder, 1893, vol. v., p. 409.
[2] Clinical and Therapeutical Journal, vol. ii., p. 735. Paris, 1894.

and feels much easier. No more vomiting. Extremities are still somewhat cold. Abdomen much distended, tense, rather hard, and tympanitic. Liver dulness entirely obscured.

3 P.M. — More comfortable. Extremities warmer. Pulse, 88 ; temperature, 99° F.

January 6th, 10 A.M.—Had another one-fourth grain of morphine last evening, and rested fairly well. Pulse, 92 ; temperature, 99.6° F. Abdomen still much distended and tympanitic, but not quite so tense and hard.

8 P.M.—Countenance better. Had one-fourth grain morphine during day. Pulse, 96 ; temperature, 100° F.

January 8th, 10 A.M.—Takes two or three doses of one-eighth grain morphine every twenty-four hours, which keeps him comfortable. Abdomen still sufficiently tympanitic to obscure liver dulness, but less tense.

Has had a nutrient enema or two, but does not retain them. May have two drachms of milk and lime-water every half-hour.

January 10th.—Abdomen now quite soft, but still tympanitic. Pulse, 80 ; temperature, normal. May have half an ounce of milk and lime-water every half-hour.

January 15th.—Doing well, abdomen quite flat, complains a little of flatulence after milk. Relieved by maltopepsin.

January 23d.—Going about the house, but has more or less dyspepsia.

In 1886 I saw him at his old employment, still complaining of his stomach.

In 1889 the patient died with symptoms of perforation after a day or two's illness. I did not see him, as I had removed to Toronto.

CASE II. February 4, 1892, 12.15 A.M.—M. H——, aged twenty-two, female. General servant, always healthy till three years ago, when she had an attack of severe dyspepsia, which kept her in bed for three months. Became very pale and thin at this time. Has suffered every year since, for a few weeks, with pain after eating and sometimes with vomiting ; never raised blood.

A week ago had quite a severe attack one day of pain in left epigastrium, accompanied with eructations of wind.

The present illness began just as she was retiring to rest after her usual household duties, with an agonizing pain in epigastrium and left hypochondriac region, and was accompanied with vomiting of her evening meal, which consisted of hard-boiled eggs and bread with raisins in it.

When I visited her, about an hour after the seizure, she was suffering acutely with pain in upper abdomen and on left side, running through to back. Extremities were cold ; abdomen hard and tender, especially in left upper part, but not much distention nor tympanites ; breathing thoracic ; pulse, 90 ; temperature 98° F.

After two hypodermics of $\frac{1}{4}$ grain morphine each, she became easy. Ordered $\frac{1}{4}$ grain morphine *p.r.n.*, and a teaspoonful of cold water occasionally to relieve thirst

9.30 A.M.—Slept fairly well without further opiate. The attendant, contrary to instructions, gave a few teaspoonfuls of milk a short time ago, which caused some pain ; $\frac{1}{4}$ grain morphine given hypodermically. To adhere strictly to the drachm doses of water. A bed-pan to be used for urine.

8.30 P.M.—Had one dose of morphine two hours ago for pain. Dozing. Abdomen rather less tender and hard. Pulse, 122 ; temperature, 100° F. ; respiration, 35.

February 5th, 9 A.M.—One-fourth grain morphine at midnight. After that rested well. Abdomen more distended and tympanitic than yesterday, but less tender and softer. Pulse, 132 ; temperature, 100° F. ; respiration, 33. A hypodermic injection of $\frac{1}{4}$ grain morphine given.

11 P.M.—Had three or four doses of morphine since morning. Raises wind occasionally. Pulse, 138 ; temperature, 101.6° F.

February 6th, 9 A.M.—Three doses of morphine in night. Pulse, 140 ; temperature, 101.5° F.

11 P.M.—Menstruation began this afternoon, two weeks before time. Has had more than a grain of morphine to-day. Tympanites is getting more marked. Gas passes freely downward. Pulse, 140 ; temperature, 102° F.

February 7th, 9 A.M.—Rested well. Three half-grain morphine suppositories used in night. Says she feels better. Pulse, 130 ; temperature, 101° F.

February 8th, 9 A.M.—Had five suppositories of morphine since yesterday morning. Rather restless night. Pulse, 140 ; temperature, 102° F. Epigastrium very prominent and tympanitic. A hypodermic needle thrust in and much foul gas escaped with relief.

7 P.M.—A pretty comfortable day. No opiate. Pulse, 124 ; temperature, 101.6° F. ; respiration, 26.

February 9th, 9 A.M.—Had restless night, some delirium. Took one-half grain of morphine by mouth. Complains of pain in top of left shoulder. Feels hungry. Pulse, 138 ; temperature, 102.2° F. May have a teaspoonful of milk and lime-water every half-hour. Epigastrium again punctured with good effect.

Patient grew worse during the day, the pulse running up to 144. At 8.30 P.M. I made a small opening in prominent epigastrium and let out about two quarts of sour greenish fluid from the peritoneal cavity. Drainage-tube inserted. Dr. J. H. Burns gave chloroform and rendered other assistance.

February 10th.—Patient sank during the night, with constant delirium, and died at 6.30 A.M., being the seventh day of illness. No autopsy.

CASE III. September 18, 1894.—I. D——, aged twenty. Female servant. Usually well, with the exception of dyspeptic symptoms on and off during the last three or four years. Never laid up by them. Can never eat meat without suffering. Has frequently vomited after meals. During the past month, and especially for a week back, has been troubled very much with her stomach, although not enough to prevent her performing the customary duties of a general servant.

At her dinner, at 2 P.M., and at 6.45 P.M., was suddenly seized with very severe pains in left epigastrium and left hypochondriac region. This was accompanied with pain in the top of left shoulder ; and she vomited about a pint of thin sour fluid.

I saw her within an hour, and found her moaning with pain ; extremities somewhat cold and clammy ; left upper abdomen somewhat hard, tender, and slightly increased in resonance, without noticeable distention ; and with decubitus on back, knees being straight. Pulse, 88, of fair strength ; temperature, 99.4° F. ; respiration, 28.

After two hypodermics of one-fourth of a grain of morphine I left her fairly comfortable. To have only drachm doses of cold water, and $\frac{1}{4}$ grain morphine *p. r. n.* To keep perfectly quiet, and use bed-pan if necessary.

At 10 P.M. she was quite easy, two doses of morphine having been taken by the mouth. No more vomiting. Pulse, 116 ; temperature, 100° F. ; respiration, 30.

September 19th, 7 A.M.—Had a quiet night, sleeping at intervals, no further opiate required. Breathing continues to be thoracic. No further distention. Left upper abdomen still tender on motion or pressure. Pulse, 92 ; temperature, 100.2° F. ; respiration, 28.

Considering an operation advisable I had her removed in an ambulance to St. John's Hospital at 8 A.M.

10 A.M. *Operation.*—Chloroform by Dr. G. B. Smith, assisted by Dr. J. H. Burns. The usual antiseptic precautions having been taken, I made an incision from four to five inches long in the middle line of the epi-

gastrium. On getting into the peritoneal cavity, a few ounces of turbid serous fluid escaped, and the somewhat distended stomach presented. This I carefully drew up into the wound. While doing so, I felt some adhesions giving away in the direction of the pylorus, and then that part came into view. Its peritoneal covering was red and much thickened, having several shreds of the same character hanging from it and partly surrounding an opening of the size of a quill in the stomach-wall. The perforation was situated near the gastro-hepatic omentum and not far from the pylorus. A probe passed readily into it, and a drop or two of fluid escaped.

I now introduced two sutures of fine silk with a common sewing-needle close to the margin of the opening, and tied them, thus snugly closing it. Outside of these I placed five or six Lembert sutures of the same material. Several times the thread cut through the soft thickened peritoneal coat, but finally I succeeded in getting a sufficient number to hold, my assistant keeping the folds of the indurated coats of the stomach-wall close together until all the sutures were tied.

I then gently cleaned the surface of the stomach with a soft sponge, and closed the abdominal wound with silkworm gut sutures. No washing out of either the stomach nor peritoneal cavity, and no drainage. Iodoform gauze dressing.

During the operation the patient vomited about a pint of greenish fluid.

5 P.M.—Vomited once since operation. This caused considerable pain. Two hypodermics of $\frac{1}{8}$ grain morphine have been given. Has had an enema of beef-tea and brandy. Temperature rose to 102.4° F. at 2.30 P.M. Is now 101.8° F.; pulse, 104. Gets a teaspoonful of cold water occasionally.

September 20th, 10.30 A.M.—Had a third dose of $\frac{1}{8}$ grain morphine at midnight. Has vomited several times, and then complained of considerable pain in neighborhood of wound. Slept three or four hours during night; nutritious enemata are given every six hours and are retained. Pulse, 82; temperature, 99° F.

September 21st, 11 A.M.— No further opiate required. No vomiting since yesterday afternoon. Had four hours sleep during night. Pulse, 88; temperature, 98.8° F.

September 22d, 10.30 A.M.—Slept four or five hours. Pulse, 88; temperature, 99.2° F. Rectum was washed out with warm water last evening. Bowels moved well. As nausea had ceased, may have $\bar{3}$ j. of cold water every half-hour.

September 23d.—Doing well. Pulse, 76; temperature, 99° F.; to have two drachms of milk and lime-water every half-hour.

September 24th.—Menses appeared last evening. They were due about the time perforation occurred. Pulse, 76; temperature, 98.6° F.

September 25th.—Doing well. Has a little flatulence at times. Pulse, 76; temperature, normal. Ordered five grains bismuth subnitrate four times a day.

September 28th.—Patient takes a considerable quantity of milk and junket now. Pulse and temperature as before. Omit nutritive enemata, which had been given only twice a day of late. Sutures all removed yesterday. Transferred to the general ward to-day.

October 1st.—Patient takes about thirty ounces of milk and a pint or more of junket every day. Has no dyspeptic symptoms whatever. Bowels are moved every other day by enema.

October 8th.—Doing well. Has a quart of milk, a pint of junket, a few soda biscuits, and the white of one or two eggs per day. May get out on couch.

October 17th.—Has been going about the ward for several days, and left for home by train to-day. To continue present diet, chiefly, for several months. Has not felt any discomfort at all from food for two or three weeks.

Remarks.—I think no one can doubt that the first case reported was an instance of recovery from perforation by a gastric ulcer. Unfortunately, however, it is more than probable that the same ulcer or another one brought about a fatal issue by a subsequent perforation.

In the second case we have the patient living till the seventh day after this occurrence. My experience in the first case led me to hope for a possible recovery in the following one, especially as the symptoms of shock, distention, etc., were not nearly as marked as in the patient who recovered. After losing this patient I determined that I never would trust to the powers of nature in a similar case again, but do an early laparotomy and suture the opening in the stomach.

As it was after dark when I first visited the third case, I thought it advisable to wait till morning before operating. When morning came, and I found the patient had passed such a comfortable night and was then feeling and looking so well, with little or no abdominal distention, I had half a mind to postpone surgical interference. But the remembrance of my preceding case, with her apparent improvement after morphine and rest, warned me that too much reliance could not be placed upon any such temporary lull in the symptoms, and I therefore had her at once removed to hospital for operation.

As there was so little of the stomach-contents or of inflammatory material in the abdominal cavity, I did not deem it necessary to wash it out. Neither did I attempt to clear out the stomach itself, because it would have been impossible to have done so via the perforation without the escape of some of its fluid into the peritoneum, and I did not think it of sufficient importance to demand the use of the œsophageal tube for that purpose. Possibly, by emptying this viscus, less strain would be put upon the sutures in its wall, but in the present instance they must have borne that strain well, although the patient vomited a number of times after the operation.

In view of the fact that a very small per cent. of cases of gastric perforation from ulcer recover, and some of these after long and continued suppuration and discharge, we think that most medical men will agree that when the diagnosis is reasonably certain, a laparotomy should be done, and that with the least possible delay. As far as I have been able to glean from the reported cases, none has made a good recovery when twenty-four hours or more have elapsed between the onset of the symptoms and the operation of gastrorrhaphy.

In conclusion, let me draw attention to the pain that was complained of in the top of the shoulder in two of the cases reported. Mr. Gilford reports, in the London *Lancet* of June 2d, another in which pain, in the top of both shoulders, was a prominent symptom.

Pain in this locality is not, however, necessarily diagnostic of gastric perforation only, for I recently operated on a ruptured tubal pregnancy, where there was acute pain in both shoulders the day before operation.

Transplantation of the Human Cornea.—At a recent meeting of the Vienna Society of Physicians, Professor Fuchs exhibited a case of transplantation of the human cornea. It is well known that Professor Hippel has succeeded in transplanting pieces of the cornea in four cases; but the pieces of cornea that he transplanted were small, while Professor Fuchs used flaps of from four to five millimetres in diameter. Large pieces of the cornea, when transplanted, do not become opaque so soon as small ones. The pieces for transplantation used by Professor Fuchs in this case were taken from a human eye. Four weeks had elapsed at the time of exhibition since the operation had been performed, and the piece implanted was perfectly transparent, while in previous cases the opacity had commenced after the tenth day.

A CASE OF TETANUS WITH DEMONSTRATION OF THE BACILLI; TREATED WITH INOCULATIONS.[1]

By W. GILMAN THOMPSON, M.D.,

NEW YORK.

The patient was a schoolboy, thirteen years of age, admitted to the Presbyterian Hospital in August last. Previously he had been in ordinary good health. When I first saw him his condition strongly suggested hysteria, or rather one of those cases of hysterical or pseudo-rabies which are not uncommon, and there was a history dating back for several years of occasional fits of hysterical laughing, coughing, and crying, with violent outbreaks of passion. The subsequent course of the disease, however, fully established the diagnosis of tetanus, and this was further confirmed by finding the specific bacillus.

The following data, which have been kindly furnished me by the House Physician, Dr. Thornley, were noted on the boy's admission:

Three weeks ago, while getting over a fence, the patient stepped on a spike which penetrated his shoe and made a wound in the ball of his right foot. A poultice was applied and the wound healed quickly. About a fortnight after the injury he began to complain of pain in the foot. The next day the leg grew painful so that he limped very much in walking. The thigh and hips next became painful, and the whole limb stiff; general pains were also noticed. Two days ago he first complained of stiffness in the jaw. He had been told that he was going to have "lock-jaw," which alarmed him and his family, so they brought him to the hospital. His symptoms became rapidly worse, and on admission frequent clonic spasms of all the muscles appeared with some opisthotonos, but no general convulsions. The jaw became set and the boy was unable to swallow. He also developed general anæsthesia. Physical examination showed nothing of interest beyond the nerve-muscle symptoms. The patient was somewhat emaciated but not anæmic. The mouth could only be opened about three-eighths of an inch, and this effort caused decided risus sardonicus. The thoracic and abdominal muscles were prominent and subject to spasms of board-like rigidity. The major muscles of both lower limbs became rigidly contracted upon slight irritation. There was intermittent contraction of the extensor longus pollici in both legs, with some slight dulness of sensation over this region. Deep reflexes not obtainable. The pupils were regular and reacted normally.

The symptoms were evidently exaggerated by observation (for the boy swallowed without difficulty a glass of milk which was left beside him), yet the means ordinarily employed to detect hysteria failed of effect, and convulsions could not be excited by any reasonable degree of peripheral irritation. The patient grew worse, and during the following week reached a condition in which the muscles became so rigid that he was unable to make any voluntary movement at all. Tetanic contractions were always present even during sleep, but whenever the slightest stimulus was applied, such as the change in temperature or weight produced by removing the bed clothing, or by tapping on the chest, the entire body became as rigid as a board. In fact the boy could be lifted completely off the bed, by raising the toes of one foot, so that the only support of the body was at the occiput.

A peculiarity of this condition was that the patient repeatedly said that he had "no pain at all." When one recalls the intense pain of a "cramp" in the calf of the leg which sometimes seizes a person at night, it seems incredible that tetanization so severe as to throw every muscle into strong relief should exist for hours continuously without producing any pain or even soreness. Spasmodic jerking and twitching of the muscles did occur frequently, and at times affected the whole body, and these spasms were often preceded by a cry of pain very closely resembling that of hydrocephalic children, and which sometimes occurred during sleep; but uninterrupted contraction, no matter how severe, was not painful, even when so strong that the arms, which were kept flexed across the chest, could not be extended short of the use of force which would have fractured them. Another very curious fact in connection with this disease is that no degree of continued electric or other stimulation, applied physiologically to muscles either directly or through their nerves, is capable of maintaining a muscle in tetanus more than a few moments at a time. Relaxation from fatigue inevitably follows. But in this case the rigidity was absolute for hours together. The diaphragm and the tongue seemed to be the only voluntary muscles not affected. The breathing consequently became wholly diaphragmatic, and the boy was able to swallow fluids which were poured between the set teeth.

The electric reactions of the muscles were tested with the following results: The minimum galvanic current of a dry silver battery which produced perceptible muscular contractions was, for the masseter, 15 cells; right arm, 9 cells; left arm, 10 cells; right leg, 23 cells; left leg, 19 cells. The infra-maxillary muscles were strongly and painfully contracted with 25 cells, but the jaw was not opened beyond the usual three-eighths of an inch. Other symptoms which predominated were constipation, incontinence of urine, excessive perspiration, and fever.

The following notes are copied from the record of the fourth day after admission, or the ninth day of the disease:

"Profuse perspiration exists. The patient cries continually for water, which he swallows with difficulty. Spasms more frequent, twenty or thirty occurred in the night. During intervals muscles still stand out prominently and are relaxed to some extent, but not wholly. Arms are becoming more involved in spasms. Abdominal muscles very distinct, more rigid than any others. Feet are flexed and markedly inverted; the first phalanx of the toes is extended; the others are flexed. Patellar reflexes are lost."

On the thirteenth day of the disease the patient became much worse, owing to progressive exhaustion and emaciation. The temperature, which had not previously been above 102.5° F., suddenly rose without chill to 106.8° F., with a very feeble pulse of 164 and respirations of 45. There was repeated projectile vomiting and the patient was evidently *in extremis*. There was delirium, and the spasms were very frequent and severe.

At this time I succeeded in obtaining from the Loomis laboratory a tetanus toxin, made after the method of Brieger, that is, it was developed by growing fresh tetanus germs in a strong bouillon, and the boy received daily, for five days, inoculations of from one-half to one cubic centimetre, which were placed in the gluteal region. Before the inoculations were given various anti-spasmodic remedies were tried, such as chloral, morphine, urethan, conium, etc., but all were practically without effect upon the muscular rigidity. On one occasion I ordered a very hot bath, 105° F., hoping that it might relax the spasms, but the result was so unsatisfactory that it was not repeated. The arms were completely relaxed in the bath, and remained so for some minutes, but the pulse rose to 200 and became very feeble. While the disease was at its height, nutrient enemata were given, for mouth-feeding became very difficult.

Much interest attaches to the question whether the inoculations benefited the patient or not, and I confess myself somewhat in doubt in regard to it. They certainly did no harm, and in each case were followed by a fall in temperature, excepting after the last inoculation, when it rose a degree and a half. The patient

[1] Read before the Practitioners' Society, New York, November 2, 1894.

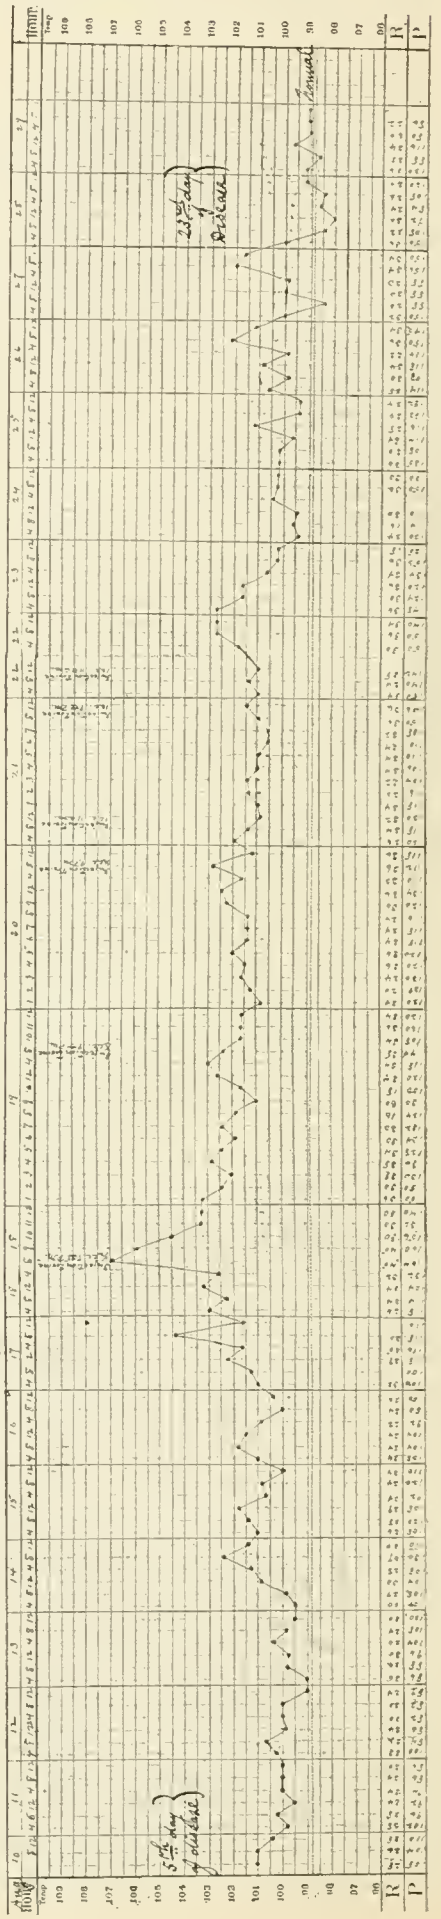
was almost moribund, with a temperature of 107° F. and a pulse of 164, when the first inoculation was given, and next day he was decidedly better, although the tetanus and muscular spasms continued for five or six days longer before they began to diminish. This all may have been merely a coincidence, but according to Gowers, only ninety per cent. of all cases recover without inoculation, and Dean states that the tetanus mortality in the London Hospital, for the past sixteen years, has been eighty per cent. Recovery is certainly very rare after the symptoms have become as severe and the exhaustion as great as in this case, which lasted for two months before the tetanus entirely disappeared.

Never having employed the toxin before—in fact I believe it had not been previously given in this city—I was cautious in its administration, and no doubt gave smaller doses than were necessary, not over 1 c.c. being injected at a time. From inoculations made upon animals with the same toxin, it seemed less powerful than I supposed, and it had perhaps deteriorated in the daylight, as it is said to be very susceptible to the chemical rays of the sun. It was originally derived, however, from a very virulent case, and was the only specimen obtainable in town at that time. It would be a matter of great accommodation if bacteriologists would keep all the new toxins and antitoxins on hand ready for immediate use.

The subsequent history of the case is uneventful. The symptoms subsided very gradually, the rigidity of the jaw slowly lessened, and the muscles of the legs were the last to relax. A spastic condition of one of them continued for some time after the patient was up and about the ward, and the right foot retained the position of talipes equinus. The delirium, vomiting, thirst, and perspiration also slowly diminished, and the fever, which had been of a continued type for a fortnight, subsided completely upon the twenty-third day. After two months the boy wholly recovered.

I was very anxious to have the diagnosis confirmed by bacteriological examination, and Dr. Connolly, of the Bacteriological Department of the University Medical College, kindly assisted. He made cultures in two agar and two bouillon tubes, from blood taken from the immediate vicinity of the scar on the boy's foot, the original wound having healed, but they gave no result. We then drew three drachms of blood from the patient's median cephalic vein, and injected this beneath the skin of a rabbit. No result was produced, and the animal remained as lively as ever. This was not necessarily discouraging, as the tetanus bacilli are not usually found free in the blood, and at the time of the latter experiment (the twenty-second day of the disease) the toxins in the blood were probably not strong. I then asked Dr. Connolly to examine the soil in the yard in East Eighty-first Street, where the boy received his injury, and after diligent search he succeeded in getting tetanus cultures from scrapings made about the hole in the boy's boot, at the point where the iron fence-spike had penetrated in going into his foot. Specimens of these bacilli, some showing the typical spores, are to be seen under the microscope.

It is now just ten years since tetanus was shown by Rattone to be an infectious disease, capable of inoculation from man to the lower animals. The pure cultures of the bacillus were first obtained by Kitasato five years ago. Its natural habitat appears to be the upper layers of the soil, especially in towns and suburban districts. Sternberg produced tetanus in a rabbit by inoculation with mud from a street gutter in New Orleans. Its common occurrence among the fishermen along the Shrewsbury River, near Seabright, N. J., and in some parts of Long Island, is familiar. The tetanus bacilli form straight thin rods which have rounded extremities that sometimes project into long threads. The spores form at one extremity of the bacilli, and as they are spherical and rather larger than the latter, each germ with its spore looks like a small club.



The bacilli grow readily in various common culture media, both with and without oxygen, and at ordinary temperatures, the best being from 36° to 38° C. Cold below 14° C. checks their growth. According to Kitasato, the spores develop in from a day and a half to a week, depending upon the nature of the culture medium. They do not grow well in blood-serum. The spores have been proven to remain capable of development even after two months of drying, and Turco has demonstrated that they withstand a five per cent. carbolic acid solution for fully ten hours. They die in three hours in 1 to 1,000 corrosive sublimate solution, but the addition of weak hydrochloric acid kills them quicker.

Kitasato has derived pure cultures of the bacilli from the pus of inoculation wounds. Brieger, in 1886, isolated a crystallizable toxin, which he named "tetanin," and his work was confirmed by Kitasato and Weil. This toxin is fatal when inoculated, but a still more powerful tox-albumin has more recently been isolated by the same bacteriologists, which destroys guinea-pigs, mice, and rabbits when inoculated. It is a product which rapidly loses its virulence in sunlight.

Kitasato, to whom we owe much of the best study of these tetanus poisons, has succeeded in rendering both rabbits and mice immune by repeated inoculations with the tox-albumin; and two other experimenters, Tizzoni and Cantani, have immunized the dog and guinea-pig.

Kitasato failed to find the bacilli in human blood, but its toxins are undoubtedly present, for he succeeded in killing mice with tetanic symptoms produced by inoculation of very minute quantities of the blood—only 0.2 to 0.3 ctgr.

Two interesting cases of inoculation with the tetanus antitoxin are reported by Dean and Evans, respectively, in the *British Medical Journal* of September 15, 1894 (pp. 579 and 581). The patients both recovered after severe symptoms had developed. The dose injected was 2¼ gm. Tizzoni gives the maximum dose at 4.5 gm.

NERVOUS DYSPEPSIA.

By H. ILLOWAY, M.D.,

NEW YORK.

FORMERLY PROFESSOR OF DISEASES OF CHILDREN, CINCINNATI COLLEGE OF MEDICINE AND SURGERY; FORMERLY VISITING PHYSICIAN TO THE JEWISH HOSPITAL, ETC.

Nervous dyspepsia, though a well-established category of gastric disturbance, the one of the many dyspepsias that has maintained its place despite the later investigations and researches on the functions of the stomach, and consequent establishment upon a more scientific basis of the pathological processes proper to it, and though much has been written upon it, is still to-day a jumble of all sorts and most varied morbid states: Reflex gastric irritation, organic disease of the nervous system, hysteria, neurasthenia, general intoxication of the system, etc.

Leube,[1] in his first communication to illustrate and more clearly define what he understood by nervous dyspepsia, relates two cases, one in which there was an enlarged spleen, and as no examination of the blood was made at the time, it is impossible to say whether this enlargement was due to malarial intoxication or to some affection located essentially in the blood; we can assume that either one or the other of these two conditions was present, and the remedies successfully employed for the relief of the case, quinine and iron, will support such an assumption. In the second case there was undoubted pregnancy, for the woman aborted, apparently in consequence of an intra-uterine examination, and immediately thereafter her gastric trouble began to improve, and in a short time she was well. On another occasion[1] he stated that he included in this group all the cases of dyspepsia that arise in any way from direct or reflex irritation of the gastric nerves, from pregnancy, from diseases of the female genital organs, from intoxications of the system, from organic or functional diseases of the nervous system, from constipation. According to others,[2] the entozoa may be a source of nervous dyspepsia. Glax,[3] Burkart,[4] hold nervous dyspepsia to be but one of the symptoms of that disturbed condition of the general nervous system known as neurasthenia, and Burkart proposed the name of neurasthenia gastrica as better and more expressive of the pathological condition present. Ewald[5] upholds this position: Nervous dyspepsia is but a phenomenon of neurasthenia, and he maintains, as did Burkart, that the term nervous dyspepsia should be discarded, and in its stead the more significant one of neurasthenia dyspeptica adopted. He prefers the qualifying term dyspeptica for the reason that generally both stomach and bowels are affected at the same time. Leyden,[6] though holding the view that the disease is due to a pathological condition of the general nervous system, contends strongly, nevertheless, for the autonomy of this category. However, from his etiology of the affection, from his further description of it where he quotes freely from Beard, and from the therapy recommended, it is evident that, with the exception of his refraining from the use of the word neurasthenia, he is in full accord with Burkart, Ewald, Beard. Herzog[7] says that in all cases of nervous dyspepsia we have either hysteria or neurasthenia. Bouveret likewise identifies nervous dyspepsia with neurasthenia.[8]

As a necessary consequence of this grouping together of different morbid states, the symptoms of all these have been thrown together and described as the symptomatology of nervous dyspepsia. We have thus all the symptoms that may be encountered in neurasthenia, in hysteria, and, in addition, according to Leube, symptoms resulting from pathological processes altogether different from these. The picture resulting is indistinct, blurred; so much so, indeed, that Leube himself says that the diagnosis nervous dyspepsia is a matter of impossibility, while Leyden, who believes that it can be made, admits that it is possible only in this way: When you have treated a patient for a considerable length of time and cannot arrive at a clear conclusion as to his case, you may call it nervous dyspepsia.

The object of all classification and grouping together of objects and phenomena that present themselves to us being that we may the better recognize and the more quickly grasp the origin, the nature, the relationship to others of a given object or phenomenon, it is, *a priori*, necessary that such group or class shall have certain fixed landmarks, certain traits, certain characteristics, by which a group or class can be recognized, and by which it can be distinguished from another and different group. In so far as medicine is concerned, it will certainly be admitted that any classification that does not convey to the mind any distinct idea as to the etiology, pathology, *modus curandi* of the group, that does not furnish us with characteristic traits by which such a group can be recognized, cannot at all be regarded as a classification, in fact is no classification, nothing more than what I designated it at the outset—a jumble.

To Leyden belongs the credit of being the first to fix a limit to this apparently boundless and chaotic category. It is well known to all, in fact, a rather ancient usage, that when in speaking of diseases we make

use of the qualifying term nervous in conjunction with the name of any particular malady, we mean to describe a complex of symptoms for which we cannot account by any anatomical changes in the organs of the body visible to the naked eye or demonstrable with the microscope. On this basis, which he says is correct and can be accepted by us, he excludes from the group of nervous dyspepsia all those morbid conditions of the stomach which, though they may be chiefly due to the nerves, are connected with anatomical processes in the nerves (sympathetic included), or can with great probability be referred to such. There are thus excluded from the category of nervous dyspepsia the *crises gastriques* of tabes. The affection of the stomach in morbus Addisonii is most likely dependent on some change in the nerve tissues, and must also be excluded.[1] Upon this same ground we are fully justified in excluding the reflex gastric disturbances due to pregnancy. Whether there is any direct lesion of the nerves in these cases has not yet been sufficiently determined. Jürgens found in a case of hyperemesis gravidarum total degeneration of the plexus of Meissner and of that of Auerbach.[2] Be this as it may, this is positive and beyond question, that we have an anatomical change in a certain organ, physiological, it is true, that must in some manner affect the nerves thereof.[3] Certainly the dyspepsias concomitant with diseases of the female genital tract are dependent upon anatomical processes which involve, more or less, the terminal nerve-filaments of the various organs.

Furthermore, the well-known rule or usage referred to by Leyden has greater scope, indeed, than he has set for it, and when we use the qualifying term nervous, we mean that no structural changes can be found to account for the symptoms presented, not alone in the solid tissues, but also in the blood. This is right ; we know that in diseases of the blood the whole organism is more or less affected ; that, in fact, changes in the anatomical constitution of the blood are equivalent, in so far as the production of morbid phenomena is concerned, to anatomical changes in the solid tissues. We must, therefore, exclude the dyspepsias of anæmia, leucocythæmia, etc. There is the further reason for this exclusion, that they cannot be said to be absolutely dependent upon the nervous system. The secretion of the various organs is derived from the blood, and when this latter is at fault, the former must be defective, and impairment of function naturally results.[4]

At the present day, neurasthenia is a well-established morbid entity, with certain definite and characteristic symptoms. It is also well known, and was pointed out by Beard [5] long ago, that, like other organs of the body, the stomach may be implicated, or even that the symptoms presented by it may be the chief phenomena in a given case of neurasthenia. Now, it is certainly more than needless, nay, it only tends to confusion, to create a separate group and call it nervous dyspepsia, which may mean something else, when what we really want understood thereby are the gastric disturbances of neurasthenic or hysterical individuals. Surely the contention of Burkart and of Ewald, as already mentioned, is more than justified, and the stricture of Rossbach cannot be gainsaid.[6] There is still further reason for excluding the dyspeptic complications of neurasthenia or hysteria. It is a generally admitted fact, as can be readily learned from the writings upon this topic, and I can affirm it from personal observation, that in the dyspepsias of neurasthenia or hysteria, the stomach requires no attention on the part of the physician ; the neurasthenia only, the faulty condition of the general nervous system, need be treated. When this is improved, the dyspepsia will be better ; when the general nervous system has recovered its normal tone, the dyspepsia is cured. It is thus very evident that these gastric symptoms are but part and parcel of the neurasthenia, and not the expression of an idiopathic affection of the stomach. Such clinical evidence is of importance in the study of the natural history of obscure ailments, and cannot be disregarded.[1]

The question that now presents itself is very naturally this : What is nervous dyspepsia ? To answer this is the object of this paper, and for the purpose of greater lucidity I shall describe to you what my experience and study have led me to regard as nervous dyspepsia, after the method that has become classic in the description of disease.

Keeping in mind the limitations set forth above, there results to us as a definition of the disease the following : Nervous dyspepsia is an ailment of the stomach without any definite and fixed pathological or anatomico-pathological characteristics, dependent solely upon the nerves of the stomach. The stomach is primarily affected. If any symptoms on the part of the general nervous system present themselves, they are the consequences of an irritation proceeding from the stomach, and are therefore but secondary manifestations. The treatment must be directed to the stomach ; only in that way can the disease be quickly and surely relieved.

Symptomatology.—There is no nausea. There is no vomiting, usually. There is generally no bad taste in the mouth. The tongue, on rising in the morning, is covered with a thin white coat ; this coating looks as if saliva had been brushed over the tongue—not like the coating of fever ; it is transparent, and the red color of the tongue beneath can be clearly seen through it. There may or may not be elongated papillæ at the tip ; in the majority of cases that came under my observation they were to be seen. In fact, they were most frequently seen in this, very rarely in the other forms of gastric trouble. At times a little blister will be found on the tip or on the lateral border of the tongue ; it is more frequently seen on the tip.

The patient complains of a lack of hunger, but he eats nevertheless. His food, while eating, tastes good to him, and, once started, he can eat as well as the next man ; when he stops, however, then his misery begins. He has a feeling of fulness in his stomach ; it feels as if it were distended. Occasionally, but more rarely, there is a sense of weight in the epigastrium, a feeling of oppression.

He has eructations, and these are usually followed by a feeling of relief which lasts but a very short time—a few minutes. This belching, repeated at intervals more or less long, continues for an hour and a half to two hours. It is very different from the eructations observed in hysterical patients, who belch almost continually both before and after eating, and in whom the eructations come out in rapid discharges like the continuous cracking of a whip-cord. Moreover, in the hysterical the eructation is not attended by any feeling of relief.

But the most unpleasant in the whole train of symptoms is this one, which is perhaps best described as a condition of general irritability. Some of my patients have described it as a state in which they feel like the proverbial Celt who is just aching to have somebody tread on the tails of his coat ; they would like to have a row with somebody ; they would fight with the whole world. Others have said that they feel as if they just want to be let alone with their stomach ; anything and everything irritates them ; a question addressed to them ; a question asked and a prompt or satisfactory answer not at once forthcoming ; loud talking ; singing ; music. Some describe it as a queer sensation in the head. It is not a headache ; it is not a pain, by any means ; it is a feeling of heaviness of the head, of weariness of the

[1] Verhandl., etc., loc. cit.

brain; at times a sensation as if the brain were irritable. Sometimes the irritability, the unpleasant sensations in the head, may so preponderate that the patient loses sight of his stomach. This feeling of irritability continues for an hour and a half to two, occasionally even to three hours; then, as the distress in the stomach abates, it also disappears.[1]

Two to three, or even four, hours after meals, according to the quantity and character of the food that the patients have eaten, after the symptoms just described have to a great extent abated, the patients experience a gnawing feeling, a craving sensation, in the stomach, which is relieved by food taken, but is again followed by the feeling of distress and irritability. It is not a *heisshunger*, a bulimia, as described by Leyden, for the patients have no hunger, and a little food, very little indeed, as I have found—a tablespoonful or two of milk, even a tablespoonful or two of cold water—will completely allay it, with the advantage that no distress will follow. There is no thirst. The bowels are generally undisturbed, *i.e.*, they retain their former habit. Where the psyche of the patients becomes so impressed by their ailment that they give up, in a measure, their usual habits of exercise, the bowels, which were previously regular, will become costive.

Patients generally follow their usual pursuits; even women who have onerous household duties to perform are able to do so, and do so despite a certain amount of physical and psychical depression. Some patients, more particularly females, whose habitual diet is a rather vicious one, *e.g.*, the typical American menus, if the disease runs untreated for any length of time, or if not properly treated, will become hypochondriacal, melancholy, and lose all interest in their usual activities.

The majority of this class of patients are incapable of doing any mental work, studying, prolonged thinking; their brain tires very easily and quickly; light, amusing novels, such as are designated in German "Lustige Erzählungen," novels that require no mental effort, are read with pleasure and even with benefit, even by those who complain of great brain weariness.

The sleep is always undisturbed. Only exceptionally, and then only in cases of long standing, is there any complaint of inability to sleep. Despite the fact that the patients take food in sufficient quantities, they emaciate notably. I have observed that, as a rule, these patients cannot tolerate strong alcoholic liquors; brandy or whiskey, if taken, is almost immediately rejected. Sometimes even milder drinks, as wines, are not well borne. There is no tenderness on pressure on the pit of the stomach. Flatulence has been counted among the symptoms of nervous dyspepsia. In my experience I have found flatulence in catarrhs of the stomach and in intestinal indigestions, but never in nervous dyspepsia, where the stomach alone is affected. Congestions to the head I have never observed. It may be that the feeling of weight in the head, the inability to do mental work, have been regarded as due to congestion, or perhaps the flush of the neurasthenic has been mistaken therefor.

Etiology.—Two etiological factors have stood forth prominently in the cases that have come under my observation, and it has always been the one or the other to which the patients have ascribed their ills, viz.: 1, mental shock; 2, tobacco-smoking.

Mental Shock.—It is not necessary for me to go into details here as to how shock affects the organism. That it does so is well known. To this one point, however, I would call your attention, namely, that the shock may have either a general or a limited effect; that in the one instance a neurasthenia may be developed, and in the other a nervous dyspepsia. I do this for the reason that mental shock is set down as one of the principal etiological factors of neurasthenia, and hence a wrong inference might be drawn as to the nature of the cases observed by me. In neurasthenia the whole nervous system is affected as a result of the shock, and with it the nerves of the stomach. The patient continues under the depressing influence of the shock; he does not rally therefrom. It may be exemplified thus: If it has been a financial shock that the patient has suffered, he will be constantly bewailing the loss of the money; will have gloomy forebodings as to his future business prospects, as to the future of his family. If it has been a death, he will appear inconsolable; he will talk about the deceased at all times; will weep and lament; be gloomy and given to dark and desponding thoughts. In nervous dyspepsia the patient recovers quickly from the shock. He is not depressed any more by the pecuniary loss; his grief over the death of a dear one is assuaged, and his system would be at its normal were it not for his stomach. Upon this organ, which, as is well known and as has been often set forth, is readily affected by psychic influences, the whole force of the shock seems to have been expended; it continues in a morbid state.

The differences here pointed out are clearly demonstrated by the conduct of the patients themselves; thus, while in the first case the patient will not be able, in his own judgment, to follow his usual avocation, will sit around and mope bewailing his lot and complaining of a thousand ills, in the second instance the patient will follow his usual pursuits, and only when the gastric trouble has long continued and his system has broken down, as shown by the emaciation, will there be noted a disinclination to attend to business, to accomplish the usual duties, a depression, a tendency to melancholia.

Tobacco-Smoking.—I do not at all refer here to those instances that are occasionally seen by almost every physician, in which from the large quantity of tobacco consumed in one way or another the system has become intoxicated, and gastric disorder, as one of the manifestations of such intoxication, appears. Though this latter is also a result of a morbid state of the nervous system, I exclude it nevertheless from the category of nervous dyspepsia for the reasons already given above, that it is but part and parcel of a distinct general morbid state, and that for its relief no special treatment of the stomach is requisite. The cases I refer to are about as follows: The patient is a moderate smoker: he smokes four to six cigars a day, and never, as he believes, suffers in any way therefrom. But his stomach troubles him. He eats a good dinner, and, feeling good, naturally wants a cigar and gets it. After he has smoked one-third, one-half of the cigar, he has uneasy sensations in the epigastrium; his food, which he did not feel before, now lays like lead in his stomach; he wants to belch and feels that a good eructation would give him relief. Occasionally there is pyrosis. He has that feeling of general irritability that is so difficult to describe and which finds its most excellent illustration, according to his own history, in Carlyle. Some have a feeling of dizziness, of weight, in the head, as has been described above; they are unable to think; they feel as if they cannot attend to their business properly. After a few hours the distress is allayed, to return again with the after-supper cigar.

Heredity.—In a few of the cases coming under my observation of the class produced by mental shock, there was a history of a father or mother having at one time or another suffered from gastric derangement. However, the percentage is too small to attach much importance thereto. Some of the very worst cases had no such history.

Pathology.—It is a rather difficult matter to describe the pathological process that is active in nervous dyspepsia, a disease without any anatomico-pathological basis. I am held that, with the exception of the nervous phenomena, the act of digestion was perfectly

[1] I have observed this same symptom quite frequently in dyspeptic infants. I shall recur to this more in detail on another occasion.

normal. He arrived at this conclusion from the fact that on examining the stomachs of such patients seven hours after a test-meal they were found empty.[1] Ewald and Leyden hold that this is not sufficient evidence to prove that the digestion proceeds normally.[2] Herzog, who has more recently studied the chemismus, found the conditions rather variable. In some cases there was hyperacidity, in others subacidity, and again in others the acidity was normal. These varied conditions were associated with diverse conditions of the motility.[3]

In the cases reported by Boas[4] in his recent book, there is a similar absence of anything like a positively abnormal condition of the chemismus. In my own experience I have found that these patients were always able to digest nitrogeneous food well, in fact that it agreed with them better than substances of the other alimentary groups. This clearly proves that a sufficient amount of HCl and of pepsin were present in the gastric secretion. In the last two cases that I had occasion to examine more fully, in accordance with modern methods, I found the total acidity rather high, though still within the normal limits as determined by Ewald and Boas.[5] The same variability has been found in the motor power of the stomach. Leube[6] holds it to be normal. Herzog[7] has found it both subnormal and normal. Bouveret[8] maintains that there is atony of the whole gastro-intestinal tract. It must be borne in mind, however, that Herzog and Bouveret refer chiefly to cases of neurasthenia in which there is a general depression of muscular irritability. So far as my own experience goes I have never found any atony of the stomach, and I have most carefully examined for it. Judging, however, from what I have experienced in my own person, having suffered from the disease for quite a time, I should say that at the outset, immediately after the patient had finished eating, there seems to be an inhibition of all muscular action of the stomach, as if it were paralyzed. This inhibition lasts for a longer or shorter period—half an hour to an hour and a half—then ceases, and it has seemed to me that with the resumption of muscular activity the general phenomena begin to abate. In some of the cases coming under my observation, especially in those due to tobacco-smoking, I judged from the description given me that a like condition was produced in them.

Upon this point there is no disagreement that in nervous dyspepsia there is nothing abnormal in the chemismus, and likewise the motor power cannot be said to be to any degree impaired. Wherein, then, lies the difficulty? All else being excluded, we naturally look to the nervous system.

It can be assumed with a great deal of certainty that the sensory nerve of the stomach, the vagus, is in a state of hypersensitiveness, of exaggerated irritability, which manifests itself upon the ingestion of food by the pressure thus produced upon the ultimate nerve-filaments. The sense of weight, the feeling of pressure, the uneasy sensations in the stomach, the fact that food that taxes the stomach much causes greater distress than such as does not, all point plainly thereto. This irritation is transmitted to the nerve-centre, thence to other cerebral centres, and we have as a resulting manifestation the general irritability already described, and occasionally certain other phenomena which more properly pertain to neurasthenia or hysteria (hyperæsthesias, feeling of heat and cold as in malaria, fibrillary tremor of tongue, feeling of palpitation, etc., globus, œsophagismus, hysterical ructus, paræsthesias, etc.). It can be very readily understood how, if the true character of the ailment remain unrecognized, or if it be not properly treated, the irritability may wax so great as to cause emesis, so that the greater part of the food is rejected almost as soon as taken or shortly thereafter. It also explains why these stomachs do not tolerate strong alcoholic liquors.

[5] Ibid., Th. i. [6] Loc. cit. [7] Loc. cit. [8] Loc. cit.

I have already stated that I believe, judging from my own personal sensations and confirmed by those of others, that an inhibition of all muscular activity of the stomach occurs at once upon the close of the meal. If such an arrest does take place it naturally involves a closure of the pyloric orifice. This would account for the feeling of distention of the stomach—the patients call it bloated—and for the relief afforded by belching; the gases produced in the process of digestion not being able to escape through the pyloric orifice distend the stomach and cause distress, and their discharge by eructation naturally brings relief. Upon the conditions already set forth, the occurrence of such a temporary arrest of muscular activity is very probable and not difficult of explanation. The irritation travelling through the vagi to the brain-centres, may have an effect upon the stomach similar to that which we see produced upon the heart when an interrupted current is sent through said nerve.[1] This irritability is the sum and substance of the pathology of nervous dyspepsia.

This view was, with some modifications, advanced by Leube in his first communication on this subject,[2] though he seems to have receded therefrom in his subsequent address on this same topic before the Congress für innere Medizin, 1883.

As to the causes of this hyperirritability, they are, of course, the etiological factors already named. As to mental shock, although we do not know by what manner of process it acts upon the human system, we do know that it does so act, and that it is through the nervous system that its influence is made manifest. The effect appears to be rather varied in its nature. It may show itself in disturbed function of one or the other organ.

The sudden disappearance of all hunger, of all appetite, upon the receipt of evil tidings, and the marvellous rapidity with which good news will change a person who has been depressed for months, is a matter of general knowledge. Numerous observations are extant of its influence upon the liver, as to disturbance of the biliary and of the glycogenic functions.[3] It may show itself by abnormal states of the nervous system, hysteria, neurasthenia, melancholia, etc. It is, therefore, not at all far-fetched to assume that a state of hyperirritability of the gastric nerves should have been produced thereby, more especially as the stomach seems to be the organ upon which the effect of the shock was chiefly expended.

That tobacco-smoking may affect the stomach has long been known. Without laying any especial stress upon the experimental results obtained in animals, the experiments partaking more of the nature of acute poisonings, I would say this much from careful clinical observation: In some cases in which the digestion was of normal character, smoking a cigar shortly after a full meal gave rise to the sense of weight, of fulness, of oppression; it seemed (and this I have myself experienced) as if the digestive process had been at once arrested; there is the same feeling as if the muscular activity of the organ had been inhibited, and as a result thereof the fulness, the distention. Smoking several hours after full meals can produce a like effect, plus, in some individuals, a pyrosis. There is secreted, under its influence, an acid fluid which causes a burning sensation in the pit of the stomach, and if regurgitated will set the teeth on edge. Smoking upon very light meals, after coffee, will with some persons cause pyrosis.[4] Smoking immediately before meals may destroy the hunger, banish all appetite; if the person eats nevertheless, he will most likely have a whole train of unpleasant sensations. I have known smoking to produce cardialgia. As to its action upon the nervous system, I

[4] That smoking may excite pyrosis is mentioned in Der Tabak u. seine Einwirkung, Ludwig Jankau, München, 1849. Richardson: Diseases of Modern Life.

have observed, in connection with the dyspeptic phenomena the general irritability already described. I have noted dizziness, vertiginous sensations, and general tremor. Schotten[1] reports that he has observed hyperæsthesia of various nerve-tracts produced by smoking: he has also noted the vertiginous feeling and a hyperæsthesia psychica; disturbances of motility, muscular spasm, tremor, etc. Gilbert reports a case of what he calls "hystérie tabagique."[2] Strümpell cites tobacco-smoking as one of the etiological factors of various maladies of the nervous system.[3] That tobacco-smoking has a special predilection for the vagus nerve, is shown by the many cases of dyspepsia and the striking cases of tachycardia, reported by numerous authors, and a number of which I have myself seen. It can therefore, in view of all this, be assumed, and the assumption is fully justified, that a state of hyperirritability of the sensory nerve of the stomach has been developed, and that the pathological process is the same here as already described. The assumption is fully borne out by the symptomatology, and furthermore all the manifestations described are understood and accounted for.

Diagnosis.—Although, as already stated, both Leube and Leyden held that it was impossible to make a diagnosis of nervous dyspepsia, I firmly believe that, within the limits set down, and bearing in mind the nature of the ailment and its symptomatology as already described, there can be no difficulty in making an exact diagnosis, and from the outset. With the present methods of examination and our advanced knowledge of gastric pathology, it is almost impossible, I hold, to mistake nervous dyspepsia for ulcer of the stomach or gastric catarrh, and *vice versa*. One, two, at most three, careful examinations with acquisition of the previous history will soon set us right. There is therefore no necessity for going into detail as to the differential diagnosis between them. The only form of gastric disturbance with which it can be confounded is what, with Burkart and Ewald, I would call neurasthenia gastrica, and from this it can be differentiated by the following and divergent characteristics:

Neurasthenia Gastrica.	Nervous Dyspepsia.
The patient feels bad when his stomach is empty; after he has eaten he feels much better, much stronger.	The patient is at his worst after eating.
He usually does not care to eat; his food, he says, has no taste for him.	He wants to eat; he likes to eat—though he is not hungry—for his food tastes good to him.
If he has any distress after eating it can be banished at once by diverting his mind to some other matter.	It is possible to a certain extent here, but the diversion must be of the greatest interest so as to occupy his whole attention, and must do so for at least two hours.
Frequently bulimia.	Never.
There is generally more or less complaint made of the bowels; sometimes it is a girdle feeling (somewhat like that of tabes); soreness, weight, pains, etc.; a complication of neurasthenia intestinalis with neurasthenia gastrica.	Patients never complain of the bowels in the way described. The only complaint they occasionally make is that they are constipated.
Despite his assertions that he has a bad stomach since a long time, and that he must be very careful in what he eats and eat but little, he generally eats well and usually maintains his weight. From external appearances nobody can believe his stomach at fault. Occasionally his statements are true; he eats but little and loses flesh.	The patient loses flesh and if the disease continues for any length of time he emaciates markedly.
The sleep is disturbed; it is interrupted. He dozes and feels somebody touch him, hears somebody speak to him, feels as if he were falling into an abyss, and wakes up with a start and cannot go to sleep again.[1] Or his bed will not let him sleep.[2]	Sleep is usually undisturbed. If disturbed it is only in this way: the patient is sleepless. When he once goes to sleep, however, he sleeps soundly.
Patients have sensations of heat and cold, so that sometimes they believe that they are suffering from malaria.	
The patients are depressed and languid; they cannot follow their vocation, cannot attend to their duties.	Patients can attend to their duties, and do so. It is only just after meals, when the distress and irritability are at their maximum, that the dyspeptic has any feelings akin to those of the neurasthenic.
The patient has a thousand and one ailments besides that of his stomach; he has headaches, he has pains in his head, pains in his back, soreness of the shins, etc.	He complains of nothing but his stomach. Sometimes the irritability described may preponderate in the patient's estimation, so that he will lose sight of his stomach, but a few questions will bring him back thereto.

In a word, in neurasthenia gastrica more or less of the characteristic features of neurasthenia are always present.

Prognosis and Duration.—The prognosis is set down by eminent writers as very unfavorable; taking my own experience into consideration, and it has been sufficiently large to justify my expressing an opinion, I must say that the prognosis of nervous dyspepsia, as described here, is decidedly a favorable one; even in cases of long standing, if the proper methods be employed recovery will ensue, and in comparatively short time, as can be seen from Case I. In all my experience I have had but one case of nervous dyspepsia that I failed to relieve, and this was a person of gluttonous habits who informed me that she would never submit to any dietary regulations and deprivations.

As to duration, that varies. The trouble cannot be said to have a fixed limit of time, in the sense that it runs its course and then abates, as for instance typhoid fever; the duration of nervous dyspepsia is dependent upon the following circumstances: whether the true nature thereof is promptly recognized by the physician; whether it is properly treated; whether the patient has sufficient self-control to observe the strict dietary regulations necessary to his recovery. Thus it will be seen that in Cases I. and VI. the disease lasted a long time, though the duration was short after the proper treatment was instituted; Cases III. and V., which came very soon under observation and were at once appropriately treated, were of rather short duration.

Complications.—I have never observed any, except a slight eczema on the chin, which requires no especial attention and which disappears as soon as the stomach is better.

Sequelæ.—It has been said by good authority that nervous dyspepsia may result in severe and even dangerous forms of gastric disease. So far as my own experience goes, I have never observed any of these dangerous sequelæ; even cases of very long standing have made a comparatively quick and good recovery. I believe, however, that, given a predisposition thereto, insanity of the melancholy type may result. This belief is not based upon any personal knowledge, but solely upon the observation, rather frequently made, that these patients incline to melancholia, and from reports of insane asylums.

Case I.—Mrs. K——, aged thirty, consulted me in Cincinnati, October 25, 1885. She walked very feebly into my office, dropped into a chair, and closed her eyes as if she were about to faint. I ran quickly for some Hoffman's anodyne, ordered some cold water to be brought, etc. The lady, however, soon opened her eyes and said I need not feel alarmed, that she was not going to faint; continuing, in a very low tone of voice,

[3] Specielle Pathologie, etc.

[1] See Lowenfeld, Pathologie u. Therapie der Neurasthenie u. Hysterie.
[2] I mean by this that though he be ever so sleepy while sitting up, sleep flies from him as soon as he lies down in his bed.

so low that I had to lean forward in my chair to catch what she had to say, she informed me that she really thought it useless to consult any more doctors as she knew that she was in the last stages of consumption, and that all efforts to cure her would be futile. She had come only because her husband had insisted that she should consultme.

History: Mrs. K—— is from New York City, having lived there for over seven years, from the time of her marriage up to within two weeks of the date given, when she joined her husband in Cincinnati, where he had established himself in business. She has been married seven and a half years, but is as yet childless. Already in her maidenhood she was occasionally troubled by her stomach; occasional attacks that would last but a short time and disappear. As to the nature of these early attacks I could learn nothing definite. She seemed to have no distinct ideas either as to the symptoms that were produced, as to the length of time they lasted, or as to the length of interval at which they appeared. After marriage the attacks came on more frequently and grew more severe. During this illness, which has lasted the whole period of her married life, she consulted some of the most reputable physicians in this city. She consulted first the well-known general practitioners, who all advised the free use of alcoholic stimulants, brandies, wines, etc., good nutritious diet, and plenty of it. The opinion was expressed that she was either on the verge or already affected with phthisis pulmonalis. She was advised not to sleep on feather-beds, to avoid dust, etc. Later on, upon the advice of relatives, she consulted several eminent gynecologists, the female relatives having been of the opinion that her stomach trouble was due to some uterine complaint or to her sterility. She saw some quite eminent men, whom she named to me, and heard various opinions as to the nature of her trouble and as to what she might expect. Upon this, however, they were agreed, that she would have to undergo a serious operation, as all her ailments were due, according to one to the uterus, according to another to the ovaries Some thought that she might become fecund after prolonged treatment, others declared that she was permanently sterile. She wandered about thus from one physician to another without being benefited. She consumed, and still consumes, large quantities of alcoholic liquors, two to three bottles of brandy per week, and four to five bottles of good Rhine wine. The liquor bills are so large that Mr. K—— says they keep him poor. She takes milk freely in the shape of milk-punch and otherwise. At the outset of her sickness she vomited very rarely, but since several years she vomits almost every time that she takes food; liquors especially are quickly rejected, almost as soon as swallowed.

Status Præsens.—Mrs. K—— is a tall woman, five feet seven inches in height; large-boned; she is extremely emaciated, does not weigh more than 85 to 90 pounds; her face is thin and peaky; the skin is dry and has a dark-yellow teint; her cheek-bones stand out prominently; her eyes are unnaturally large and have large rings around them; her lips are thin and pale; when she speaks her gums are entirely visible, they are very red in color and soggy in appearance, very much like what is seen in scurvy; her teeth are bad. She is so weak that she can hardly drag herself along.

Examination.—Lungs perfectly sound, although the respiratory murmurs are feeble. Heart normal, heart's action very weak, as in greatly enfeebled persons. Pulse 65, weak and easily compressible.

Abdomen: As she expressed herself, she has no belly at all; the abdomen presents a scaphoid appearance, the walls having fallen in so as almost to lie upon the vertebral column. A careful examination revealed nothing abnormal. The epigastric region was carefully palpated throughout its whole extent; nothing was discovered: no pain was elicited on pressure. As she had already seen so many gynecologists and they had differed in opinion, I concluded to dispense with an examination of the genital tract, as evidently not much would be learned therefrom. The tongue presented a very thin white coat, and upon the tip a few elongated papillæ were noted. Bad taste in the mouth. While she eats the food tastes good to her, and she can eat as much as anybody; but when she ceases eating then comes that miserable feeling of weight, a feeling of oppression which is momentarily relieved by an eructation; then comes an uneasiness, a restlessness over the whole body; this all continues until the greater portion of the food is vomited. The emesis is hastened by the brandy or whiskey which she generally takes with the view of relief from the distressful symptoms recounted. There is no globus, no headache. The depression that exists is due to the belief impressed upon her by physicians that she is afflicted with an incurable disease. There is some tenderness of the shin-bones, there is some rachialgia; this is, however, undoubtedly due to the fact that the muscles of the back are greatly wasted, and that it requires great efforts on the part of the patient to hold herself erect. Her feet are nothing more than skin and bone, and consequently walking in the thin-soled shoes worn by ladies is exceedingly painful to her. An examination of the stomach contents was left in abeyance, as the general condition of the patient would not warrant it. The question of the presence or absence of HCl in the gastric juice I would determine by dietary methods. She sleeps badly, that is, she sleeps only in short snatches; she cannot sleep two hours at a stretch.

Despite her marked emaciation and the greatly debilitated condition of the patient, I put her upon a rigorously restricted diet in accordance with the rules I had formulated for myself in the treatment of such cases. Medication was but trivial. The whole treatment was a local one and directed solely to the stomach.

December 2, 1885.—The treatment has been perseveringly followed; the patient feels much better. She has improved greatly in her general appearance, and her face and figure both show that she is gaining in flesh. She is much easier after meals—in fact, the previous unpleasant sensations after eating are now almost altogether wanting. She sleeps well, stools (which I always direct to be carefully inspected) are normal. About this time she requested that I make some change in her diet, and I permitted the use of chopped raw beef in place of the meat that she had been taking till now. Some additional change was also made in her drink.

December 20th.—Patient informs me that she has seen some white bands in her stool. She was directed to bring some for examination. They were the proglottidæ of the tænia medio-canellata. The raw beef was immediately discontinued, but owing to her still weak condition I did nothing toward expelling the worm. About the first of February, the patient having gained greatly in strength, I prescribed an emulsion of pumpkin seed, followed this up with some kousso, and she expelled one piece about twenty inches long, and the following day a second piece ten inches long. The proglottidæ showed that the worm was still young. No more was seen after this.

March 15, 1886.—The patient is doing very well; she is much fuller in the face, rounding out in the abdomen, and altogether has gained considerably in flesh. At the end of April, 1886, Mrs. K—— informed me that she was pregnant, and in the beginning of February, 1887, she was delivered of a fine, healthy boy. Mrs. K—— has since continued to do her duty as a good wife, and has presented her husband with four healthy children. She is now living in a large city of the State of Pennsylvania, and is in good health and condition.

Case II.—Mrs. R——, aged fifty; woman of five feet

five inches in height; well built; of good muscular development. Mother of four children—two boys and two girls, all grown. She has a prolapsed uterus, for which she wears a ring pessary which is removed once a year, and not returned for eight to ten days, in which time she keeps her bed. She has a very mobile, nervous temperament. She has had many struggles in this life on account of a husband who was given to spendthriftness; and a son, who was a good-for-nothing and, still worse, caused her great grief. She is generally a lively woman, loves to go out and visit, and to enjoy some of the good things of the world. She is a very active woman, attends to her whole household, doing her own work, cooking, cleaning, etc.

In January, 1889, I was called to attend Mrs. R—— for an acute laryngitis. At this time she was also under treatment with a gynecologist for the prolapsed uterus. I treated her for about a week, and the case not progressing satisfactorily I advised her that it would be best for her to place herself in the care of a throat specialist and left the case. My advice was not followed; the gynecologist treated her laryngitis; she used liniments that blistered her neck and kept it raw for nearly six weeks. She was confined absolutely to her room for four full weeks. About March 1st I was called again. I found her very much depressed, melancholy, given to tears, to dark broodings, etc. Not being able to elicit much, I took it for granted without further examination that she was hysterical and told her so, and prescribed some tincture of valerian. Her confidence in my medical skill was now greatly weakened, and upon the advice of friends she placed herself in the care of a quite eminent neurologist. She was medicated, treated with galvanism, with static electricity, shock to the spine, etc. She was ordered to eat plenty of good nutritious food.

About the early part of June I was called again—at this time I did not know that she had been in the hands of a nerve specialist; I did not learn this until some time after the patient had fully recovered. I found her as I had seen her before, melancholy, despondent; her face expressive of gloomy thoughts and dark forebodings; she cried much and readily. She spent most of her time on a chair or on the lounge, and appeared to have lost all energy for work and all desire for dress. Her pulse was slow and weak. She slept badly, she could not go to sleep on account of the gloomy thoughts that troubled her. She was losing flesh rapidly, and was very much thinner than when I had seen her in March. She ate fairly well—she had always been a hearty eater. Bowels sluggish. Questioned more closely, she informed me that at the time when she was confined to her room something had occurred that had troubled her greatly in her mind, had called back the business reverses of her husband—she was the financial manager of the family—and that her appetite, which had already become poor from the confinement, was then altogether lost. She ate, however, as usual, perhaps even more frequently, as she felt weak and wanted to gain strength. After eating she felt badly; she had a sense of oppression and weight in the pit of her stomach; she wanted to belch, and belching always gave her a little relief. She always felt more despondent after eating; she was very irritable then and could not bear to have anybody talk to her. This fact that she was always at her worst after meals was also observed by the daughter, a very intelligent and cultivated young lady.

A physical examination revealed nothing; the chemismus was not investigated, as the patient would not allow it. I did not insist, for to me the diagnosis was clear. That the chemismus must be of normal character I judged by the fact that, though the patient took large quantities of food, there was no dilatation and no diarrhœa. The tongue was coated with a white coat, looking like a layer of saliva.

The plan of treatment that had given such an excellent result in Case I. was prescribed for Mrs. R——. In addition to this I directed that she resume her previous habits of exercise, working about the house, going out shopping, or promenading. To allay the gnawing sensation, which she felt some hours after meals, she must take nothing but two table-spoonfuls of milk, or the same quantity of ice-water.

She observed the rules and regulations carefully for two weeks and was doing very nicely, being greatly improved physically and psychically, when she concluded that she might allow herself greater liberties in her diet. This over-indulgence brought its own punishment with it. There was an immediate return of the previous distressing sensations; she became despondent again; in short, she relapsed into her former state. I was called to see her. Surmising the cause of her relapse, I questioned her whether she had not disregarded her dietary regulations; she denied absolutely that she had done so, but her daughter happened to come into the room just then, and to my question replied that her mother had been grossly disobedient; that a constant watch had to be kept upon her to make her observe the rules of treatment; that on that day, the daughter being compelled to go out, the mother took advantage of her absence and ate what she called a square meal. I gave the daughter the necessary directions; the mother I lectured upon the folly of her conduct, painted in dark colors what would be the result of following her own bent, and in bright tints the reward of obedience. In two days she was better.

July 5, 1889.—She continues to improve rapidly. The unpleasant sensations consequent upon eating have almost entirely disappeared; she is in good spirits and attends to her duties as before; she sleeps well. Her face shows a gain in flesh. Treatment, with some slight modifications, to be continued.

August 1st.—Patient is doing excellently; she is regaining flesh and strength rapidly. The nervous phenomena have disappeared entirely. With some advice as to her diet and some other things pertaining to the *modus vivendi* for the next few months, I discharged her cured. She has continued in good health, and has had no further trouble with her stomach.

Case III.—Miss M——, aged thirty; of ordinary stature, about five feet in height, and rather poor in flesh now. She has always been hale and hearty and of a merry disposition; never knew what it was to have nerves. She is a teacher, and taught school up to within a short time.

October 14, 1882.—Some months ago she had some great trouble, the exact nature of which I could not learn, and since then she has been greatly depressed, melancholy, in fact. She will not go out, and avoids all society. At one time she had pains between the shoulder-blades, but that is gone now. She sleeps well, but only for a few hours. She has no hunger, and therefore does not want to eat; her family, however, insists upon her eating, and when she has once begun to eat she can keep right on, as the food tastes good to her; but when she is through, then she wishes she had not eaten at all. She has then a sense of fulness as if her stomach were distended, a sense of weight in the epigastrium, which is relieved for the moment by an eructation. There is a general uneasiness of the whole body that will not allow her to sit down, but keeps her moving up and down the length of the room. After an hour or two, according to the character of the meal she has taken, she feels somewhat easier, and then she sits down in a corner and mopes and broods and cries. Tongue coated with thin, white, transparent coat; the papillæ about the tip are somewhat elongated. Bowels constipated. Physical examination reveals nothing abnormal. The patient was put upon the treatment usually pursued by me in these cases. In two weeks she was already much better, and in five weeks from the time treatment was instituted, the patient was discharged cured.

Case IV.—E. R——, aged fifty; man, five feet ten inches in height, broad-shouldered, of excellent physical development generally. A university man of superior attainments. He has led a very active life as a business man, lawyer, justice, and politician in the great Northwest. He is a good liver, drinks moderately, and smokes considerably. In 1870 he became the editor of a large daily paper; he continued in this position till the end of 1874, when he was forced out. He resumed the practice of the law. In 1876, having lost what little he had had, the law practice not remunerative, and the times very stringent, he had a hard struggle and a great deal of mental worry. About the middle of the year he began, for economical reasons, to make his own cigars, and these were very strong. In January, 1877, he sent for me. He complained of unpleasant sensations in his head—an inability to study. No especial desire for food, though he can eat when it is placed before him. After eating he feels very much distressed; he has a sense of weight in his epigastrium; his stomach feels as if it were distended; an eructation gives relief for the moment. Stools regular. Sleeps well. He has lost flesh. Physical examination reveals nothing abnormal. Tongue coated with a thin, white, transparent coat; some elongated papillæ about the tip and edges. As in this case both etiological factors were present, and it was a question in my mind whether one or both had produced the morbid state of the patient, I ordered, besides the usual treatment, absolute rest from mental work; no reading or studying at all; sufficient physical exercise by walking or working in the garden. At the end of four weeks the patient was very much better; at the end of three months he was entirely well and discharged from treatment.

Case V.—C. H——, aged thirty; man, of ordinary stature, about five feet six inches in height; of ordinary muscular development; light complexion. Drinks moderately, but smokes much. Usually enjoys good health, and is capable of great exertion. He went through a rather protracted siege of typhoid fever lately, but has fully recovered therefrom. He called to consult me in January, 1890. He complained that after eating he had a fulness in the stomach, a sense of weight, a feeling of distention; a voluminous eructation would afford momentary relief. He has a feeling of giddiness in the head; a general irritability comes over him, so that it is almost impossible for him to attend to business. After the disagreeable sensations described have passed, he has a gnawing in the pit of his stomach, for which he takes a little whiskey and soda. The bowels are normal. Sleep is good. He has suffered from these dyspeptic attacks for quite a number of years. I also learned that he was a good liver, liked rich food, and always smoked strong cigars after meals. He feels weak and keeps thin. A physical examination revealed nothing abnormal. I directed him to take a test-breakfast the next morning, and to be at my office an hour thereafter for examination. One hour and twenty minutes after taking the breakfast I removed from his stomach about twenty cubic centimetres of nearly semifluid material. Nothing abnormal in its appearance. The bread was well worked up with the water. Reaction with blue litmus markedly acid. Strong reaction with phoro-glucin-vanilline. I gave him the usual directions for treatment. A week later I saw him again; he was feeling splendidly, never better in his life. Three months later he called again, complaining of the same distressing feelings that had annoyed him before. I taxed him with having violated the rules of living laid down for him, and he acknowledged that he had done so; he had forgotten himself at a supper, and eaten and smoked contrary to his rules. He recovered quickly. He is in splendid condition; has grown strong and stout. He has not been troubled either in his head or in his stomach for more than a year.

Case VI.—J. W——, aged twenty-two; five feet five inches and a half in height; weight, one hundred and twenty-nine pounds. He has already weighed one hundred and thirty-two pounds. Father living, in good health, aged forty-two. Mother healthy, with the exception of a nervous headache with which she is troubled. She has such an attack once every two weeks, and these last usually one full day, occasionally two days. She is home alone the whole day and worries much. About two years ago she had some trouble with her stomach and bowels; she suffered great pain, but was well again in four days. As a child patient had measles; none of the other maladies of childhood. About eight years ago he had an attack of what the physician called neuralgia of the head; the pain was located in the occiput. He was sick about a week. About this time he became somnambulistic, and walked almost every night; when he did not walk he would shout and raise a rumpus generally. The physician who attended him at the time said that his somnambulism resulted from a disordered stomach; he himself, however, was not at all conscious that his stomach was any way at fault. About seven years ago he had granulated lids; two years ago he was again troubled in this way. He has some hypermetropia and wears glasses. A year ago he had an attack of what was called rheumatic grip; he was confined to his bed for three days; on the first day that he was up his brother was seized with congestion of the brain; his mother coming into the room and finding the boy in that state, gave a succession of screams that frightened him, so that he fell over on his face in a spasm. He did not lose consciousness altogether; he was again confined to his bed for three days, and the doctor who visited him said that he had fever. Twice gonorrhœa; the first time a year ago, the second time five months ago.

About five years ago, one Sunday, in the midst of his dinner he suddenly had a feeling of weight in his stomach, as if lead were lying there. He had to stop eating then and there; shortly thereafter he was seized with cramps in his bowels. This became a sort of habit with him, and he had cramps after every meal; he had to go to stool and then the pain ceased. Sometimes, however, a queer sensation remained for a time. He treated himself with home remedies; he had considerable intervals of freedom from suffering. At the end of a year and a half he was altogether much worse, and concluded to consult a physician. He did so, but was not relieved; he consulted another physician, who ordered him to drink a cup of hot water every morning, and gave him some powders to aid digestion. He drinks beer, but very moderately. He smokes seven cigarettes and one cigar a day. He smokes since his twelfth year. He eats two meals a day. According to what he has been told, he has had catarrh of the stomach for the last ten years.

Present condition: Careful physical examination reveals nothing abnormal. Reflexes normal. Teeth good. Tongue coated with white fur and rather broad; some elongated papillæ at the tip. He has a bitter taste in his mouth. He has no hunger. He has a sense of weight, of oppression in his stomach immediately after eating. He wants to belch; after belching he feels easier for a few minutes. Bowels usually regular. He is down-hearted; out of humor; after eating a feeling of irritability comes over him, so that he would like to pick a fight with any and everybody. This wears off gradually. When his attention is attracted by other matters in which he is greatly interested his dyspeptic phenomena soon disappear. When he wakes up in the morning he feels badly; sometimes it is sharp pain. Stomach shows nothing abnormal; no atony.

August 27, 1894.—Withdrew from patient's stomach about 50 c.c. of residue an hour and fifteen minutes after a Boas test-breakfast.

Examination: No odor. Appearance as it should be; the bread very well worked up. (Patient is not accustomed to drinking water, not even in summer.)

Markedly acid to blue litmus. Strong reaction to Congo-red. Strong reaction with phoro-glucin-vanilline; likewise with resorcine. Total acidity, biuret reaction with $\frac{1}{10}$ normal KH solution 7.1 (for 10 c.c.). Calculated for free HCl, .25915.

An examination for pepsine was not deemed necessary, the abundance of the HCl present indicating with certainty the presence of pepsine.

None of the special tests for the motility of the stomach were made, for the reason that my patient could not spare the time. However, I consider that the examination for atony, made after the method of Boas, suffices also for this, as the motility must be good, otherwise an atonic condition would be indicated.

He was given directions as to his treatment. Six days later I examined the state of his stomach, as to motility, after the method of Leube. Seven hours after a test-meal I introduced a stomach-tube, and withdrew about 20 c.c. of rest; it was altogether fluid, except a few small flocculi that looked very much like the meat of watermelon and bread crumbs. Of the rest of the food taken, roast mutton, string beans, etc., nothing was seen. A further examination gave same results as above. Microscopic examination of the flocculi showed starch grains, vegetable fibres, and a few oil-globules.

September 5th.—The patient is doing very well; in fact he is a patient no more, as all his annoying symptoms have disappeared.

1138 Madison Avenue.

ON THE DIAGNOSIS OF PLEURITIC EFFUSION.

By H. B. WHITNEY, M.D.,

Professor of Diseases of Children and Physical Diagnosis in the Colorado State University, Denver, Col.

The object of this paper is to again call attention to the importance of percussion outlines in the diagnosis of pleuritic effusion. Owing largely, no doubt, to the varying statements of authorities, the diagnostic value of the curve which bounds an effusion is still greatly underestimated. When one considers the uniformity of dynamic conditions under which fluid collects in different pleural cavities, it is an *a priori* inference that such collections must have a uniform, and therefore characteristic, shape; and since this shape can be determined by percussion, the evidence of the latter ought to be of a most conclusive, and even pathognomonic, character. Such I believe it to be.

About the ordinary physical signs I shall say but little. While recognizing their great value, it must be admitted that none of them are pathognomonic. Even puncture with a hypodermic needle is not always conclusive. A positive result is of course final, but if no fluid is obtained the diagnosis still remains in doubt. I have punctured several times over a typical effusion before fluid was obtained. In one case, hereafter given, where the shape of the flat area had led to the probable diagnosis of effusion, the operation of a small emphysema was delayed for months because of the negative result of several punctures. The other commonly received signs of effusion are still more equivocal. Absolute flatness may be due to other conditions. Bronchial respiration and bronchophony, as heard over a consolidated lung, may be everywhere heard over a large effusion. On the other hand, respiration may be almost absent over a consolidated lung if the bronchi happen to be impervious. Even vocal fremitus, perhaps the most valuable of these signs, is of uncertain import; it may be absent in consolidation, or, rarely it is true, well marked over an effusion. Again, I have heard numerous fine moist râles over an effusion, and I have obtained fluid immediately beneath a point where a friction rub was most intense. In short, none of these signs are more than strongly suggestive, and no one of them, I believe, approximates in value to the evidence afforded by percussion.

As an effusion gradually increases in quantity, its upper border undergoes, of course, a gradual series of changes. Since, however, this border presents three characteristic types of curve according to the amount of fluid, it will be convenient to divide effusions into small, moderate, and large. The present article deals only with typical, non-encapsulated, inflammatory effusions.

1. **Small Effusions.**—In this form a small area of flatness exists behind, at the extreme base of the thorax, with or without pronounced auscultatory signs of effusion. A friction sound may be heard directly over the flat area. Respiration may be quite distinct and accompanied by distant râles.

The diagnosis of such an effusion, especially when very small, depends in the first place on the discovery of the abnormal area of flatness. This observation is not superfluous, because such effusions are frequently overlooked. The zone of flatness caused by a small effusion is often not more than two or three inches in width, and when, in percussing from above downward, the upper border of this zone is reached it is sometimes mistaken for the normal limit of the thorax. This is particularly true in the case of pulmonary emphysema, where the lower boundary of pulmonary resonance is no longer at the level of the tenth dorsal vertebra on the right and the eleventh on the left, but an inch or two lower on both sides; hence the correspondingly lower position of the effusion. Such an error of interpretation must be avoided by carefully marking the lower limit of pulmonary resonance on both sides. The difference between the two will then appear and challenge further investigation.

Now the characteristic, almost pathognomonic, feature of such small effusions is the curve of the upper boundary of flatness as determined by light percussion. This curve is shown in Figs. 1 and 2, lines 1, 2, 3, and 4, the different lines representing varying amounts of fluid. The line, beginning at the spine, extends almost horizontally for a varying distance, usually to a point at or in front of the posterior axillary line, where it drops by a rather abrupt curve to the base of the thorax. The larger the effusion (within certain limits as will presently appear), the wider the zone and the more anterior the drop. The latter may rarely reach the base as far forward as the apex of the heart.

During the many years since I first learned to look for this curve in small effusions, I have become more and more impressed with its constancy and diagnostic significance. It is the only curve which I have ever found in small effusions, and I have rarely found it in anything else. That a consolidation might assume a like contour cannot, of course, be denied. In a large number of cases of pneumonia and phthisis I have never seen it.[1]

2. **Moderate Effusions.**—I would define a moderate effusion as one in which the pleural cavity is perhaps half full of fluid. In a general way, it may be said that the upper half of the affected side is resonant, the lower half flat. Intra-thoracic pressure is positive, but not enough so to produce any great displacement of organs. Resonance over the slightly compressed lung is more or less tympanitic.

Here, again, it is the curve of the upper boundary of the flat area which is the most characteristic sign of effusion. This so-called "letter of S" curve, to which attention was first called by Calvin Ellis in the later seventies, has not received the recognition it deserves. For example, in Osler's recent "Practice of Medicine" it is not even mentioned. And yet we possess in this peculiar curve a sign of moderate effusion which surpasses all others in value, which is quite distinctive, and which is rarely simulated by any other condition.

This curve is represented by the lines 5, 6, and 7, of Figs. 1 and 2. Starting behind somewhere along the

[1] On referring to Weil (Topographische Percussion, 1880) I find that he describes a curve similar to the above for all effusions except those which are very large.

middle third of the dorsal spine, it extends first outward, then more and more abruptly upward, across the scapula to the region of the shoulder. It may, in some cases, be traced across the upper axillary region, or, if

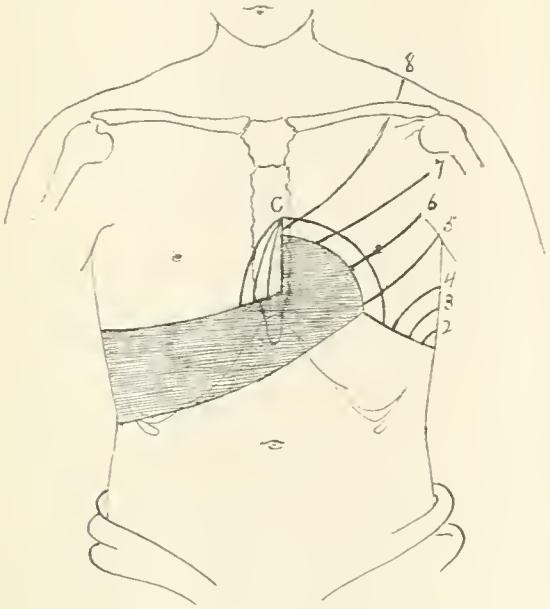

Fig. 1.

the effusion is somewhat greater, it will be lost in the shoulder or even slightly above it. These various lines are shown in the figure, the S character of the curve being more pronounced in the more moderate effusions. In front the line reappears. It may drop quite abruptly from the upper axilla to the thoracic base near the apex of the heart; or, in a larger effusion, follow approximately the course of the 4th or 3d rib. Its characteristic feature is not so much its S form as the fact that it has its highest point in the axilla, dropping slightly, at least, toward the sternum, and markedly toward the spine.

This line may be readily obtained in all uncomplicated cases of moderate pleuritic effusion. Differing, as it does, in a most striking manner from the contour of a consolidated lower lobe, it is of the utmost value in just those cases where some such aid is most needed, namely, in the diagnosis between effusion and pneumonia. In consolidation of a lower lobe the highest point of dulness is at the spine, from which it descends toward the upper axilla. The question, therefore, of resonance in the triangle A B C, Fig. 2, may decide conclusively the diagnosis between these two affections.

Why is such an important sign of pleuritic effusion still unrecognized? Garland pointed out one, perhaps the chief, reason; *i.e.*, varying methods of percussion, and failure to sharply distinguish between dulness and flatness. It cannot be too strongly emphasized that the characteristic curve of an effusion is the upper border of absolute flatness, as elicited by light percussion. If tapping lightly, the plessimeter finger is gradually moved from the area of absolute flatness toward the area of resonance, and a mark is made beneath the middle of the finger as soon as the slightest resonance is perceived, the curve can always be easily defined. Good pulmonary resonance immediately above the line is not to be reflected. The space between the S curve and the spine ("dull triangle" of Garland) is often dull, resonance over the scapula is never great, and the slight compression of the whole lung further diminishes its resonance and gives the percussion note a slightly tympanitic quality, and, therefore, higher pitch.

Another cause of the prevailing difference of opinion as regards the S curve lies, I believe, in the fact that no sharp distinction has hitherto been made between the curves of moderate and of small effusions. The believers in the S curve have always insisted that, except in very large effusions, the highest point of flatness is in the axilla. On the other hand, Wintrich, Fraentzel, and Weil, for example, state that the highest point is behind, and Powell finds a difference in different cases. I believe that in an otherwise normal chest it is simply a question of quantity of fluid. In a beginning effusion, flatness appears first at the base behind, and is bounded by the "convex curve" I have described. In a very small effusion, this curve drops in the posterior axillary line. In a somewhat larger, the zone broadens and the drop is farther forward—possibly even at the cardiac apex. If now the effusion goes on increasing, the line suddenly rises in the axilla and becomes the S curve, a change which I have hitherto been unable to carefully follow because of the rapidity with which it takes place. An effusion may be found one day highest at the spine, and on the next highest in the axilla. Why this is the mode of development I am unable to say, but I believe it to be a clinical fact.[1]

One brief case in illustration of the diagnostic value of the S curve:

M. S——, aged thirteen, had been afflicted for some time with joint tuberculosis; lungs negative. On April 15, 1893, sudden attack of pain in the left side, with difficult respiration, both lasting only twenty-four hours; no chill or rusty sputum; up and about on the second day. I was called on the 22d, when physical examination showed an area of flatness at base of left back, with slight S curve which, however, did not rise very high in the axilla and dropped to the base near the cardiac apex. Respiration over this area bronchial, with fine moist râles apparently just beneath the ear. Fremitus slightly diminished, and voice sounds somewhat distant. Diagnosis, effusion, on the strength largely of the characteristic curve. May 5th, puncture in two places with negative result. June 23d, flatness somewhat diminished, S curve less accentuated (more of an approach to the convex curve of small effusion). July 12th, line has again risen and

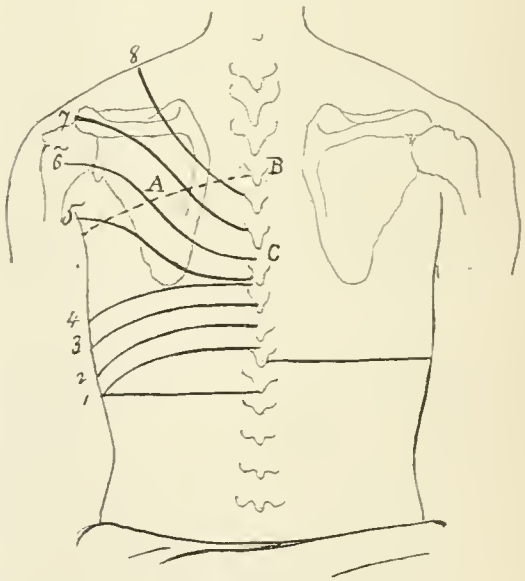

Fig. 2.

S curve more pronounced. Puncture again with negative result. September 13th, no change; no chills, and but very slight fever. October 28th, de-

[1] That the posture of the patient (erect or recumbent), while the effusion is taking place, does not at all effect the form of the flat area, is a position which I am not prepared to take. The recumbent posture may, for example, cause an earlier development of the S curve, or the drop of the "convex" curve may be further forward when the posture is lateral. In view, however, of the constancy of these two curves in moderate and small effusions, respectively, it does not seem to me that posture can be a very important element in determining the form of the flat area. I may also add that in the inflammatory effusions I have never been able to detect a change of fluid level on change of posture

cided to puncture again since I still believed there was fluid. First puncture, in tenth space behind, negative. Second, in eighth space near angle of scapula, gave pus, which was subsequently drained by incision.

In this case the curved line proved to have been a more valuable sign of effusion than even puncture, and should have led earlier to more energetic measures.

3. Large Effusions.—When the quantity of fluid exceeds a certain limit, the upper border of flatness loses its distinctive "letter of S" form, and becomes a simple curve with upward concavity. Moreover, as the lung becomes more and more compressed and crowded up toward its hilus, the difference between the absolute flatness of the fluid and the resonance over the lung becomes less marked. Still an appreciable difference usually remains, and we find that the area of flatness rises along the outer aspect of the chest, while slight pulmonary resonance is still found along the upper spine behind and in the angle formed by the sternum and clavicle in front. Lines 7 and 8, Figs. 1 and 2, show different phases of the line of increasing effusion.

It is, of course, well understood that the characteristic diagnostic feature of a very large effusion is the displacement of organs—of the heart, namely—to the right or left, and of the mediastinum, as determined by the encroachment of the perpendicular line of flatness upon the healthy side in front. The diaphragm also is displaced downward, causing on the right depression of the liver, on the left the filling of Traube's "semilunar space" and a palpable spleen. The diagnosis of such cases is very easy.

When, however, the quantity of fluid is not extreme, when the S curve is still perceptible or only partially effaced (lines 6 and 7), and when, therefore, there is as yet no pronounced displacement of organs, diagnosis is more difficult. At this stage respiration over the effusion is quite apt to be bronchial, and the extent of the area of flatness does not differ so markedly from that of a consolidated lower lobe.

It is in just these cases, when upon the left side, that a slight but easily discoverable displacement of the heart toward the right affords, perhaps, the most valuable confirmatory sign of effusion we possess. I have several times, in the past few years, called attention in a casual manner to this point. The recognition of this enlargement depends wholly upon the assumption, which I believe to be invariably true: 1. That in adult life[1] the right border of the normal præcordial area is a perpendicular line extending from the third (usually) to the sixth rib, one-half inch to the left of the median line. This I believe to be a more accurate statement than that of most authors (Weil, Cutler and Garland, Shattuck), that this line corresponds to the left border of the sternum. However, this is parenthetical, and the question is of trivial importance.

2. That under normal conditions in the adult, in the right angle formed by the upper border of hepatic flatness and the perpendicular right border of præcordial flatness above mentioned, the sternum is perfectly resonant. By "perfectly," I mean that the resonance here over its lower half is as good as that over its upper half, although, compared with normal pulmonary resonance, the note is a trifle higher pitched. This fact cannot be too strongly insisted upon. When, in an adult, there is dulness in the median line over the lower half of the sternum, as compared with the upper half, some pathological condition exists. Aside from cardiac displacement and affections of the right lung or the mediastinum, this dulness is usually due to an enlarged right heart. Less often there is pericardial effusion. Rarely, an old pericarditis has pushed back the border of the right lung, and the latter has become fixed in its abnormal position. Whichever may be the cause, it is certain that dulness in this angle is always significant. It is most easily detected by rather light percussion upon the finger carried from above downward along the sternal groove.

Now, in a left-sided effusion, this normally resonant angle is the first locality in which signs of increasing pressure and displacement are clearly manifest. The slightest movement of the heart toward the right is at once shown by relative dulness in this angle. The form of the dulness is shown in Fig. 2, the various lines dropped from the point *C*, illustrating various degrees of displacement. It is owing to the invariable position normally of the right cardiac boundary, and to the opportunity for exact and delicate percussion which this region affords, that displacement can here be readily detected at a time when that of any other organ or structure would be imperceptible. Of course, the sign is not characteristic, like the S curve. One cannot absolutely exclude a previous enlargement of the right heart or other causes of a similar area of dulness. But in the absence of souffles, suggestive history, or any other sign of complication, the coincidence of such dulness with other evidences of pleuritic effusion strengthens wonderfully the diagnosis.

It may here be mentioned that the first movement of a heart subjected to left-sided pressure is not one of rotation upon its axis. At first, the heart is simply crowded over *en masse*, the relative position of base and apex not being materially altered. Indeed, I believe that it is only exceptionally, and in cases of enormous effusion, that the heart swings upon its base, so that the apex comes to lie in the region of the right nipple. This opinion is the result both of post-mortem observation and of the clinical fact that, even in marked displacement of the heart, so as to cause a dull area on the right as far as the mammary line, the apex beat is usually heard loudest somewhere in the region of the ensiform cartilage.

In right-sided effusion displacement of the heart to the left is neither so early nor so easily detected. When it does become evident, other signs are already so prominent that it has no peculiar value.

[1] In children from the age of five to eight up to about the age of puberty, the conditions are entirely different, as the writer has attempted to show in a paper entitled "The Normal Precordia in Childhood," read before the Pan-American Congress in 1893.

Clinical Department.

IS HICCOUGH A SYMPTOM ONLY OR A DISEASE PER SE?

By HENRY LEVIEN, M.D.,

NEW YORK.

The case of "Fatal Hiccough" reported by Dr. McCartie in a recent issue of the MEDICAL RECORD, reminded me of a similar one I recently came across, but which fortunately terminated in recovery.

While hunting up the case in my record-book, I found two more interesting cases, which I would call typical, as opposed to the third one, which looked to me atypical, or one of an unknown cause.

CASE I.—Miss B——, aged twenty-two, occupation housework. On the previous evening she was taken with hiccoughs, which would come on about every fifteen minutes and continue for three or four minutes at a time. She did not sleep the whole night and wore an anxious and prostrated look. All domestic remedies tried were of no avail. I elicited the history of neurosis on her maternal side; she herself had frequent though slight hysterical attacks, and suffered greatly from dysmenorrhœa. This case yielded within a week to sedatives and antispasmodics, and isolation from her friends and relatives.

CASE II.—Miss M——, aged nineteen, shop girl, very anæmic and emaciated. During the last three years she would drop in to see me when an attack of "biliousness" annoyed her too much. The last time she called on me was on account of an intolerable

hiccough. It was indeed of a violent nature, and coming, as it often did, simultaneously with an eructation of gases from her diseased stomach, the cough could be heard at quite a long distance. Believing this case to be purely of gastric origin, I determined upon lavage and resorcin internally as an antiseptic. Within four weeks I used fifteen irrigations of her stomach, adding first sodium bicarb., later creosote to the water, when the disease abated, and she has fully recovered.

Case III.—Mr. M——, aged fifty. He met with an accident, being run over by a heavy express wagon and receiving many contusions and wounds, which were stitched up. Sedatives were required on account of the shock, which acted heavily upon him. I could not detect any internal injuries. On the fifth day Mr. M—— developed a local peritonitis in the left hypochondrial region. At this stage Dr. A. Brothers was asked to see the case with me, and he, coinciding with my opinion, did not detect any other ailment. Ice externally, and opium in full doses internally, checked the further spread of this disease, and on the fourth day the patient felt well, and both ice and opium were discontinued. An abscess which formed on the patient's knee kept him in bed, otherwise he seemed on his way to full recovery. One morning (three days after I discontinued the opium), when I called to dress his wound, I found him afflicted with hiccoughs, which followed one another in quick succession. Naturally, neither food nor sleep could be indulged in, and in consequence Mr. M—— was very much exhausted. There could be no gastric trouble, because his nourishment consisted of fluids in small quantities, nor could there be any special nervous element in this case, as he and his family were always in the best of health. I called three times during that day, and nearly exhausted the list of known remedies upon him, with but little effect. Morphine hypodermically would relieve him for a while, but as soon as the narcotic effect passed off the trouble returned with the same severity. I consulted all the reference books at my command, and finding singultus as a symptom only, I certainly could not find any suggestion how to treat hiccough as a disease. Prompt relief was necessary, as my patient was sinking. Eventually I picked up a medical formulary, and finding in its index hiccough, I was too anxious to find the panacea against this dreadful disease. What I found was calomel, recommended by Dr. Gerhard, to be given in $\frac{1}{12}$ grain doses every hour. As I had tried nearly everything but calomel, I hurried to my patient and prescribed this last remedy.

I was delighted when the report came, that after the fourth dose the trouble stopped entirely—and it did not come back. Where was the seat of the malady in this case, and in what way had the four minute doses of calomel exerted such a happy influence in cutting short this attack?

Comparing the three cases reported, I am inclined to believe that besides the typical singultus, which is only a symptom pure and simple, there exists another form of it which is a disease per se, the etiology of which is not yet known.

239 East Broadway.

ANOPHTHALMOS.

By G. STERLING RYERSON, M.D., C.M., L.R.C.S. Edin.,
Toronto, Canada.
Professor of Ophthalmology in Trinity Medical College, Toronto.

Some ten years ago I published a series of cases in the *Canada Lancet* illustrative of the anomalies of development of the eye. These cases embraced aniridia, coloboma of the iris and choroid, persistent pupillary membrane, persistent arteria centralis, and pigmentation of the conjunctiva. The publication of an example of the above anomaly by Dr. Leonard Landes reminds me of a somewhat similar case which came under my notice, but which has not been published until now. In 1871, when a student with Dr. George A. Sterling, of Sag Harbor, L. I., I went with him to see an infant which had been born the day before of Jewish parents. It was a male, very puny, with a double talipes varus. The forearms were bent inward and the hands flexed, presenting a condition analogous to club feet. It possessed conjunctival sacs, and at the bottom of them were to be seen rounded elevations, the rudimentary eyeballs. The eyebrows, eyelids, and ciliæ were normal. The child died in a few days. No autopsy was allowed.

The number of instances of total absence of the eyeballs is very small. In the great majority rudimentary eyeballs are to be found. Still rarer are the cases of monophthalmus. The conjunctival sac is always developed in some degree, as are also the adnexa. At the bottom of the conjunctival sac is to be found a round reddish-gray body consisting of connective tissue containing fat and having attached one or more rudimentary eye muscles. The optic nerve is sometimes present, oftener absent. In other instances the eyes are microphthalmic, consisting of a sac filled with fluid, and sometimes possessing a rudimentary cornea. It is curious that the eyelids, eyelashes, and lachrymal apparatus are always to be found.

ASEPTIC SYRINGES.

By THOMAS HUBBARD, M.D.,
Toledo, O.

The syringe is all but tabooed in surgery because of the useless or filthy condition of the piston packing. For some years I have been using ordinary asbestos sheeting of about three-eighths of an inch thickness as packing, and have found it very satisfactory in all respects. The disc should be cut a little larger than the barrel calibre and after it is fixed firmly by the screw-nuts on the piston one-half should be turned upward to increase suction power and one-half downward for expulsion. It is practically indestructible and can be readily sterilized. For some time after packing small fibres may be found in the fluid, but this is immaterial except in hypodermic syringes. The Overlach syringe has an asbestos packing in cement. Hypodermic syringes intended for injecting escharotics can be packed with the ordinary asbestos.

Post-nasal syringes are much improved by such packing. Mr. George Ermold has constructed one for me which is very satisfactory. The nozzle is made of aluminum and the bulbous tip has about fifteen very fine perforations. The barrel and piston are made of vulcanite. For general use these syringes should be constructed with barrel capacity of about two drachms, or have a regulator on the piston shaft. The danger comes from forcing too much fluid into the post-nasal cavity. Properly constructed and expertly used the post-nasal syringe should occupy an important place in our armamentarium.

Beer and Degeneration of the Heart and Kidneys.—Dr. Bollinger, director of the Anatomico-pathological Institute in Munich asserts that it is very rare to find a normal heart and normal kidneys in an adult resident of that city. The reason for the kidney disease is the tax put upon these organs by the drinking of excessive amounts of beer, and the cardiac hypertrophy and degeneration are secondary lesions for the most part. Formerly the population of the city was recruited by accessions from the country, but the abuse of beer has spread now to the rural communities, so that this source of healthy new blood is cut off.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, January 5, 1895.

THE PROPER CARE OF THE CITY INSANE.

THE investigation of the New York City asylums for the insane, to which reference was made in these columns some months ago, has at last come to a close, and the State Commission in Lunacy, the investigating body, has handed its report to the Mayor. In accordance with our predictions, the report fully and explicitly vindicates General Superintendent Macdonald, and Medical Superintendents Dent and Macy. But while thus praising the direct administration of the asylums, the report severely criticises the Commissioners of Charities and Correction, and unreservedly condemns the system under which our asylums, in common with our other charitable institutions, are conducted. In its main presentation of facts and conclusions as to these things, the report is unexceptionable, and must meet the approval of everyone who is familiar with the conditions under discussion.

It does not follow, however, that one must agree with the opinion of the investigating commission as to just what change in system is most to be desired. The commission recommends, as it has previously done many times, that the city asylums be transferred to the State system. Under existing conditions, the city of New York pays about $600,000 annually toward the support of the State system, getting nothing in return. Meanwhile the State insane are cared for well; the city insane, poorly. The law permits the transfer of the city insane to the State system whenever the city authorities desire it. To make such a transfer, therefore, seems the simplest solution of the difficulty; and this, as has been said, is what the report under discussion suggests.

Now it may freely be admitted that if the possible choice included only the two alternatives of leaving the insane under present management or transferring them to the State system, there could hardly be two opinions as to the desirability of immediate transfer. But in point of fact, there are other possibilities, and these are worthy of very serious consideration. Briefly stated, these possibilities are the following:

1. It is possible that the State law might be so altered that New York City would no longer be unjustly taxed for the care of insane not her own. Were this done, one strong incentive to transfer our insane to the State would be removed.

2. Movements are under way which make it not only possible but probable that our absurdly organized Commission of Charities and Correction will be so remodelled that the interests of the paupers and hospital patients and criminals will no longer be pooled with those of the insane. This accomplished, and the insane placed under supervision of a non-political Commissioner or Board of Commissioners, another very strong incentive for the transfer of our insane to the State system would removed.

Could these two possibilities become realities, as in justice they ought, there is no reason why New York City might not continue to care for her own insane, and, without expending more money than her tax-payers are at present assessed for the purpose, place her asylums on such a basis that they would compare favorably with the asylums of the State, or any other public institutions of the kind.

This, it seems to us, is the ideal to be aspired to. But if for any reason it cannot be accomplished, if the possibilities just outlined cannot be made realities, then by all means let the city asylums be made a part of the State system. That the city should pay $600,000 for the care of State insane, and only half care for its own insane meanwhile, is an injustice to tax-payers and to recipients of charity alike, that should no longer be tolerated. As has already been said, transfer to the State system would be an enormous advance upon our present method of caring for the insane. The advantages of such transfer would be even greater than at present, should the Legislature make such changes in the State care laws as seem probable. The new constitutional amendment places the Lunacy Commission on a par with the Charities and Prison Commissions. It is reasonable to hope, therefore, that the Legislature, in supplying the details as to these commissions, will follow out the implied spirit of the amendment, by making the Lunacy Commission, like the Charities Commission, an honorary board, say of five members, serving without pay, and having advisory and supervisory rather than administrative powers. Should such action be taken, properly qualified men being appointed on the new Commission in Lunacy, many disadvantages of the present State system will be overcome.

We might do much worse than transfer our city insane to such a perfected State system. But, on the other hand, we might do even better, by perfecting our own system in the way above outlined.

WINTER MEETINGS OF SCIENTISTS.

THE last week has been prolific in gatherings of scientific men. The American Physiological Society, the American Morphological Society, and the American Psychological Association have all held their annual meetings. Besides this there have been meetings of the Geological, the Historical associations, and many other learned societies.

There seems to be a tendency on the part of the associations of a purely scientific character to meet in the winter vacations, while the more practical sciences pertaining to medicine meet during the summer. Undoubtedly the winter season is the best for work, since the weather compels members to keep in-doors and puts a considerable limit upon junketing. New York, however, is almost the only city in which the physicians congregate in the dead of winter.

THE TAX-COLLECTOR AND PHYSICIANS' INCOMES.

The Treasury Department has issued a circular telling people who have incomes how to keep their books and accounts in order to make things easy and pleasant for the tax-collector.

On the credit side, this circular says, the professional man must place all his fees and all his charges for services, whether collected or not—in fact all unpaid bills—provided they are "good." We are curious to know how physicians can tell what accounts are good and what are not with any approximate exactness. Here will come merely an extraordinary temptation to underestimate the financial standing of his patients. Physicians must make up an estimate, not of their actual, but of their possible, income for the benefit of the tax-inquisitor.

THE NEW YORK CITY BOARD OF HEALTH AND SPURIOUS ANTITOXIN.

The Board of Health has adopted the following resolutions:

"That no preparation of diphtheria antitoxin shall be offered or exposed for sale in this city unless the receptacle containing such preparation has a label on which is placed a statement of the value of the contents in antitoxin, as measured by some generally recognized standard, and the name and address of the producer."

No one doubts that this resolution is in the interests of public health. But it is a curious fact that such a resolution is allowed to pass unnoticed by the advocates of personal liberty. The newspapers advertise, and drug-stores display, any number of spurious cures for cancer, consumption, epilepsy, etc, and no one protests. But the sale of a spurious cure for diphtheria is forbidden!

THE NEW YORK ACADEMY OF MEDICINE.

The Treasurer's report for the year 1894, shows the Academy to be in a prosperous condition. The total estimated assets amount now to nearly half a million dollars ($467,339.14). The running expenses amount to about seventeen thousand dollars, not including amounts spent for special purposes, such as purchase of books. The number of resident fellows is now 774, of non-resident 40, and of corresponding 7. The number of resident fellows added during the year was 40, lost by death 8, by removal or suspension 15. The report says:

"Evidences of broader influence, of higher attainment, of greater stability, must gratify observing friends of this Academy. The work which depends upon your contribution to the Treasury has not been allowed to wane. Receipts and expenditures for the Library, and general advancement, are larger than during any previous year, notwithstanding the great financial depression, which physicians have keenly felt.

"The Bureau for Nurses has been self-sustaining and added something to the Treasury. Three hundred and fifty-eight nurses have been registered, and one hundred and eighty calls for nurses have been responded to."

The condition of the Academy is evidently a prosperous one, and the profession are to be congratulated upon the renewed evidences of its successful work.

THE LIBRARY OF THE AMERICAN MEDICAL ASSOCIATION.

Seventy-four boxes of books, containing the library of the American Medical Association, have been sent from Washington to Chicago, where they are deposited in the Newberry Library. So far as we can learn, these books are practically given to this library in return for its care of them. We congratulate the Newberry Library and the Chicago profession on its accession.

We do not exactly see, however, why the profession of the whole country should establish a medical library which can never be of much service except to the physicians of one particular locality.

News of the Week.

The New Health Officer.—Dr. Alvah H. Doty, Chief of the Bureau of Contagious Diseases of the Health Department, was nominated, January 2d, by Governor Morton, for Health Officer of the Port of New York, and was unanimously confirmed by the Senate. Dr. Doty, as one of the two prominent aspirants for the position, has fairly won, and can be congratulated accordingly. Endorsed by many of the leading medical men of the city, backed by a long and creditable record as a public officer in civil as well as military life, and with a professional experience in contagious diseases that eminently qualifies him for efficient service in his new office, he will enter upon its responsible duties with the best wishes of his professional brethren and with the fullest confidence of the public. That he will deserve all we have no doubt, and we wish him every success.

Results of Serum-therapy in Diphtheria.—Dr. Sims Woodhead publishes the following table:

	Number of cases.	Number of deaths.	Percentage of mortality.	Percentage of previous mortality.
Roux, Martin, and Chaillou, Paris.	448	109	24.5	51.7
Ehrlich, Kossel, and Wassermann, Berlin	220	52	23.6	34.7
Canon, Berlin	15	3	20.0	25.0
Schubert, Berlin	34	6	18.0	
Voswinkel, Berlin	60	19	33.3	46.5
Ehrlich, Berlin	89	12	12.3	
Kossel, Berlin	233	54	23.0	
Körte, Berlin	121	40	33.1	53.8
Bokai, Budapest	35	5	14.2	53.8
Heubner, Budapest	96	37	38.5	62.5
Katz, Berlin	128	17	13.2	38.9
Aronson, Berlin	255	31	12.1	32.5-41.7
Ranke and Oertel, Berlin	19	4	21.0	
The Lancet, Austrian Riviera	70	7	10.0	
Weibgen, Berlin	65	18	28.0	40.0
Muchleck, Philadelphia	2	0	.....	Two not treated died.
Dr. White, Willard Parker Hospital, New York	32	8	25.0	42.7
Cases reported in The Lancet and British Medical Journal	79	9	11.4	

To this may be added 236 cases treated at Trieste, with a mortality of twenty-two per cent. as against fifty-six per cent. which previously prevailed.

The Medical Faculty of Bordeaux.—The Medical Faculty of Bordeaux has received from the son of a former practitioner of the town, who had exercised his profession there for more than fifty years, a donation of 100,000 francs (£4,000) toward the establishment of a Chair of Gynecology.

Immunizing against Erysipelas.—A series of very interesting experiments have recently been made by Dr. W. S. Melsome and Mr. Louis Cobbett with the object of rendering animals immune against erysipelas. Streptococcus erysipelatis is a bacillus readily capable of cultivation on beef-broth. But after a few days it is found that it ceases to grow on the broth, and dies. Why is this? Drs. Melsome and Cobbett find that the reason why the streptococcus ceases to grow on beef-broth is that the pabulum suitable for its growth is exhausted. They deny altogether that the bacillus has secreted a toxin which has caused its own death. This theory of the exhaustion of pabulum would seem to be confirmed by the fact that colonies of the streptococcus often contain a few living bacilli after most of them are dead, and if those which remain alive are sown on solid media, they give rise to new colonies at once. Animals inoculated with cultures thus produced are rendered locally and generally immune against attacks of erysipelas; but the immunity, both local and general, is of limited duration, and varies with the parts inoculated. The results obtained, though disappointing from the point of view of clinical immunization, are interesting from the standpoint of science.

The New York Times has printed and distributed among the medical profession a supplement containing a very carefully prepared account of the serum-therapy of diphtheria. *The New York Times* has shown much enterprise and scientific knowledge in its discussion of this as of other medical topics.

Northwestern Medical Society, New York.—At the annual meeting of the Northwestern Medical and Surgical Society held December 19th, at the house of Dr. Robert Milbank, the following officers were elected for 1895: *President*, Dr. J. Blake White; *Vice President*, Dr. Henry Ling Taylor; *Secretary*, Dr. Dillon Brown; *Treasurer*, Dr. Frederick Peterson.

Death of Dr. J. W. Pinkham.—At a special meeting of the Medical and Surgical Staff of the Mountainside Hospital on December 10, 1894, the following resolutions were passed:

Whereas, We, the members of the Medical and Surgical Staff of the Mountainside Hospital of Bloomfield and Montclair, N. J., have learned with deep sorrow of the death of our colleague, Dr. John Warren Pinkham; therefore, be it,

Resolved, That in the death of Dr. Pinkham we acknowledge the loss from our members of one of our ablest and most conscientious practitioners, and one of our chosen favorites both as a gentleman and a friend.

Resolved, That as members of the same profession, we unite in honoring his memory and in retaining in our recollection a kind and grateful remembrance of his many good, genial, and excellent qualities.

Resolved, That we extend our sympathies to his bereaved family, that these resolutions be incorporated in the minutes of this body, and copies of them be sent to Mrs. Pinkham, to the local press, and to the MEDICAL RECORD and *Medical Journal* for publication. John J. H. Love, *President*; Richard P. Francis, *Secretary*.

"Origin of the Term Anæsthetics"—Correction.—In article under this title, appearing in our issue for December 22, 1894, p. 799, line 12 from the bottom, for October 16, 1849, read October 16, 1846.

A Reflex of the Buccal Mucous Membrane Excited by Sulphuric Ether.—Soulier (*Sem. Méd.*, November 3d) calls attention to the possibility of combating acute pulmonary œdema by pouring a few drops of ether into the mouth, which provokes a pulmonary reflex which has as its result the expression of the contents of the lung. He tried this procedure in the case of a man in a state of agonizing asphyxia. He placed a teaspoonful of ether in the mouth and it set up an abundant expectoration, but unfortunately six hours after the patient was dead.

The New College of Pharmacy.—The handsome new building of the College of Pharmacy, in West Sixty-eighth Street, between Columbus Avenue and the Boulevard, was opened on the evening of December 28. Hermon W. Atwood, Chairman of the Building Committee, turned the building over to the Board of Trustees, in whose behalf it was accepted by Samuel W. Fairchild.

Dr. George F. Shrady then made an address in which he reviewed the steady growth and influence of the college since its organization in 1829. In fact there had been no progressive movement made in pharmacy during the last half century in which this college had not taken a more or less active part. At all times it had the sympathy, support, and confidence of the medical profession, and with its increased facilities for a thorough pharmaceutical education it was well calculated to maintain such a position for the future. He congratulated the trustees on the outcome of their persistent efforts in the erection of the magnificent edifice, the like of which was nowhere to be found.

Professor Charles F. Chandler accepted the building on behalf of the Faculty, and gave an entertaining description of laboratory work abroad. Mr. Ewen McIntyre, ex-president of the college followed with some reminiscences, after which there was a reception and collation. The Reception Committee was made up of Mr. Atwood, Professor Charles F. Chandler, Gustavus Rampsberger, Albert Plante, William Jay Schieffelin, George Massey, Theodore Louis, B. T. Fairchild, William M. Massey, Dr. Charles Rice, Dr. Adolph Tscheppe, H. N. Fraser, J. N. Hegeman, Thomas F. Main, Charles Holzauer, and Herman Graeser. The new building is of light gray stone, buff brick, and terra cotta, in the style of the Italian Renaissance. It is six stories high, and includes every modern equipment and convenience for the work of the college. The cost of the building was about $200,000.

The Association of American Anatomists held its seventh annual meeting in this city beginning December 28th, Dr. Thomas Dwight, the President, being in the Chair. Dr. F. H. Gerrish read a paper on "The Best Arrangement of Topics in a Two-years' Course of Anatomy." Among other things Dr. Gerrish said: "The problem confronting us as teachers is to discover that

plan which reduces to the minimum the necessity of knowing a good deal of every department of medical knowledge before entering upon the study of any one. I believe that every faculty should work as a team. The anatomist should precede by a day or two the presentation of the subject upon which the physiologist will discourse. The system of teaching medicine is still somewhat antiquated." Dr. Harrison Allen, of the University of Pennsylvania, brought on the collection of Indian skulls from Philadelphia to illustrate his paper on "The Value of the Nasal and Orbital Indices in Anthropology." Dr. Allen said that races can be graded by the nose. It has been generally conceded, he said, that the long, slender nose indicates a high type and the flat nose a low type of men. The North American Indians have long been represented as a race of men with long, narrow noses. They have been classified as of this type. Dr. Allen's investigations have led him to believe that this is not correct as a general classification. The skulls he has were the skulls of Indians who lived in the Delaware Valley and whose ancestors long ago were friendly with William Penn and with the Quakers. He found that the flat nose was the prevailing type. Only thirty-five per cent. of those he has examined follow the rule of long, slender noses. The Indians who made things so uncomfortable for the New England settlers, however, were of the long, slender-nosed type of men who were born fighters and were proud of it. They made an incursion into the Delaware Valley and defeated the Indians there before Penn arrived. Dr. Allen thinks that one of the explanations of Penn's pleasant relations with the Indians was that those in the Delaware Valley were of the flat-nosed low type.

Dr. Wilder, of Cornell, in discussing the "Loose Characterization of Vertebrate Groups in Standard Works," said that many books were made up of contradictions and confusing statements. "The elementary physiologies that are used in our schools," he said, "are filled with a lot of moonshine about the baleful influences of tobacco and alcoholic stimulants. We should have logic with our natural science."

Dr. Frank Baker, of Washington, said that in his experience as an editor of a scientific paper he had been shocked by the bad style and unintelligible writing of men of science. He was inclined to believe that the "pernicious habit of reading the daily papers constantly and saturating one's self with them is affecting the whole American people."

Dr. George S. Huntington, of the College of Physicians and Surgeons, read a paper on the "Convolutions of the Hemispheres of Elephas Indicus."

The American Physiological Society began its seventh annual meeting at Washington, on December 27th, with Professor H. P. Bowditch, of Harvard, President of the Society, in the chair. He read a paper, "With Regard to Representation of this Society on a Committee to Decide the Place of Meeting of the Societies of Naturalists, Morphologists, Anatomists, and Physiologists." Dr. G. M. Sternberg, Surgeon-General United States Army, read a paper on "Explanation of Natural Immunity," and Dr. William M. Porter, of Harvard, read one on "Inhibition Hypothesis in the Physiology of Respiration." Several other papers were read. The subject suggested by the council for discussion at the next Congress of American Physicians and Surgeons was "Internal Secretion of the Glands."

The American Morphological Society met at Washington, on December 27th. Dr. E. B. Wilson, of Columbia University, was elected Chairman.

Indian Territory Medical Association.—The Indian Territory Medical Association met at Wagoner, I. T., December 11th and 12th.

The Syracuse Academy of Medicine held its annual meeting for the election of officers December 4th, as follows: *President*, Dr. Alfred Mercer; *Vice-Presidents*, Drs. John Van Duyn and Ely Vandewarker; *Secretary*, Dr. T. E. Halstead.

Dr. Behring, the discoverer of the antitoxin remedy, is to be decorated with the Cross of the Legion of Honor in the New Year's list, and Paris discloses increasing confidence that the pest of diphtheria has been definitely robbed of its terrors. Drs. Behring and Roux declare that of 100,000 cases now on record there is not a single instance of the vaccine doing the slightest injury.

Tubercular Antitoxin.—The *New York Times* announces through its London correspondent that M. Roux has discovered a serum-therapy for tuberculosis. We should add that nothing could be much more improbable than that this announcement should be true. For, so far as medical knowledge goes, there is no such thing as even a temporary immunity against tuberculosis in human beings.

Obituary.

WILLIAM DETMOLD, M.D.,

NEW YORK.

Dr. William Detmold, one of the oldest and most distinguished surgeons in the United States, died of paralysis at his residence in this city on December 27th. He was the son of Henry G. Detmold, formerly Court Physician to the King of Hanover, was born in Hanover, December 27, 1808, and graduated at the University of Gottingen as Doctor of Medicine in December, 1830. After serving as army surgeon in Hanover he settled in New York in 1837, and introduced orthopedic surgery into this country.

He established an orthopedic clinic at the College of Physicians and Surgeons in 1841. In 1862 he became Professor of Military Surgery and Hygiene there, and afterward Professor of Clinical and Military Surgery.

Dr. Detmold was prominent in the organization of the Medical Corps of the United States Army in the earlier part of the war, and introduced a knife and fork for one-armed men, supplied by the United States Government as the "Detmold knife." During a surgical practice of over half a century in this city he was Vice-President of the New York Academy of Medicine, Consulting Surgeon to the Presbyterian Hospital, the first President of the New York County Medical Association on its organization in 1884, and one of the founders and President of the Society for the Relief of Widows and Orphans of Medical Men.

Dr. Detmold contributed largely to the medical journals of the country, his first publication on orthopedic surgery appearing in the *American Journal of Medical Sciences* in 1837.

Society Reports.

PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, November 2, 1894.

BEVERLEY ROBINSON, M.D., PRESIDENT PRO TEM.

Spinal Paraplegia and Anæsthesia.—DR. ROBINSON presented the patient, a clerk, twenty-seven years of age, family history negative as to neurotic taint. Patient denies gonorrhœa, but had a sore, thought not to be specific, two years ago. Slight eruption on legs one year later, and slight mucous patches in mouth. Has been treated for syphilis. Admitted to St. Luke's October 9, 1894. Had been a healthy child. Moderate beer habit. No rheumatic, malarial, cardiac, renal, or hepatic history. Had pleurisy four years ago.

Present trouble began thirteen months ago with numbness and slight loss of power in the thighs. Two days later severe cramps in calves, and in five days the left leg was completely paralyzed and right one almost so. For three weeks there was no change. Then there was gradual return of power, so that patient could walk around on crutches. During the first week there was severe diarrhœa, with loss of control of anal sphincter. Since then there has been incontinence of urine and partial loss of control of stools. There has been steady, but very slow, improvement ever since the first month, and now the patient has pretty good control of right leg, but the left leg is still very weak. There has been considerable loss of tactile sensation in both legs, more so in right. Sense of heat, cold, and pain are affected to a greater degree. Knee reflexes markedly exaggerated, more on left side; ankle clonus; rigidity of both lower extremities; no disturbance of cutaneous reflexes. Upper extremities normal. Pupillary reflexes normal. Electrical reactions normal.

Dr. Robinson said that in presenting the patient he would like to elicit an opinion as to the exact nature of the lesion producing the symptoms, and especially as to the propriety of using electricity, regarding the value of which in cord lesions there seemed to be some difference of opinion among neurologists. He said that Dr. Starr, who had examined this patient, had pronounced the case one of spastic paralysis, the lesion affecting more particularly the lateral columns of the cord, and not, if Dr. Robinson remembered his statement correctly, affecting the anterior portion. Dr. Starr, it appeared, had advised against the use of electricity, and it was particularly on the point whether this agent might not be of some use in sclerotic lesions of the cord that the speaker wished an expression of opinion by the members. He believed himself that galvanism ought to be employed in this case. Regarding the prognosis, would the patient continue to improve, or was the lesion of a nature which made further improvement impossible? On the supposition that it might be of specific origin, the patient had been treated by mercurial inunctions, iodide of potassium internally, and hot baths.

Replying to a direct question from the President, Dr. Delafield said he thought galvanism would make very little difference in the result. If the lesion were syphilitic, antisyphilitic treatment might prove of further value, but if syphilis were left out he thought the improvement would cease at a certain point. Since Dr. Starr's experience had been so much greater than his own, his opinion regarding the nature of the lesion and treatment would be of much more value.

DR. HALSEY, who had charge of the case as house-physician at St. Luke's, said that Dr. Starr thought there might be a localized pachymeningitis of the cord, and that antisyphilitic treatment might affect that, but there must also be a sclerotic process within the cord itself which it would not influence.

DR. PEABODY though electricity would have no influence on the cord lesion; that its only value would be in keeping up the nutrition of the muscles until the time when nerve-power might be restored. But in the present case it was needed for this purpose, as it had been stated the patient walked on crutches, and in that manner kept up sufficient peripheral stimulation without electricity or massage.

Later DR. DANA, in reply to a question by Dr. Robinson, but not knowing the history of the present case, said he thought electricity was of some use in certain chronic lesions of the cord, say locomotor ataxia.

Cosmetic Effect of the Knife in Lesions of Small-pox.—DR. ROBERT ABBE presented a young lady in illustration of the cosmetic effects of the knife in certain ugly lesions produced on the nose by small-pox. The pitting on this prominent feature was the worst which he had ever seen, and in order to relieve it he resorted to what, so far as he knew, was quite a novel procedure, namely, shaving off the surface of the organ down to near the bottom of the pits. The raw surface had healed without scar and had left this portion of the face less deformed than any other. Without the operation the ugliness of the nose would have made the young lady's life unendurable.

Report of a Case of Tetanus, with Exhibition of Cultures of the Tetanus Bacillus.—DR. W. GILMAN THOMPSON read the paper and made the demonstrations (see page 5).

DR. R. F. WEIR had found that during the last year some eleven cases had been treated by injections by Tizzoni and others. He had records of nineteen similarly treated cases, twenty with the one just presented, with four deaths. The dried alcoholic precipitate of serum from the immunized horse or dog had been found rather insoluble, while the blood-serum itself, or the serum dried in vacuo into scales, which is quite soluble and permanent, has proved satisfactory. Using the latter, nine out of eleven cases lately collected by him were cured. In great contrast to that, ninety-five per cent. of all cases of tetanus had died prior to the inoculation treatment. The quantity of serum injected had been from thirty to fifty cubic centimeters at a dose, or of the dried serum three to five grammes, the total amount not having exceeded 300 c.c. in any one case. It had not always been followed by reaction. The original inoculation of the immunized animal is made in the proportion of 1 gm. of serum from a tetanized animal to 1,000,000 gm. of a healthy horse, etc.

One experimenter while working on mice inoculated himself accidentally with tetanus virus, but immediately began injections with attenuated cultures, kept it up several months, and no result had followed. This method (Brieger's) is not so satisfactory as the blood-serum injections of Tizzoni and Cattani.

The dry scales are yet very expensive, costing some $40 a tube, containing 3 gm. each; but he believed this antitoxin would soon be prepared in the laboratory of the College of Physicians and Surgeons, to meet the emergencies of the profession in this city. Of course the demand for it was quite limited, as tetanus was a very rare disease. It was stated that light and oxygen were supposed to kill germs of this kind, yet peroxide of hydrogen had been found to have no effect. Later observers had declared the germ not to be an anæroid one.

DR. THOMPSON remarked that Dr. Byron had been able to keep cultures of the tetanus bacillus under oxygen.

Nephrectomy in a Case of Congenital Absence of One Kidney.—DR. F. P. KINNICUTT related the case. He had seen the patient with the surgeon to a hospital in a neighboring city. She was poor, and had been compelled because of her sufferings from a tumor of the kidney, to give up work and enter the hospital. An exploratory incision was decided upon, was made in the lumbar region, and led to removal of the kidney,

which was of horse-shoe form and had undergone sarcomatous degeneration. Absence of the other kidney had not been suspected until uræmic symptoms developed and terminated in death within forty-eight hours. He remembered that Dr. Polk had a similar experience some years ago.

Dr. Weir remarked that congenital absence of one kidney occurred once in about four to six thousand persons.

Dr. Polk said he had recently had another case of congenital absence of one kidney, but fortunately the anomaly was discovered before he took out a piece of the ureter of the only kidney, which he was about to do in an operation upon the uterus.

Syphilitic (?) Infiltration of Peritoneum following Ovariotomy.—Dr. W. M. Polk related what to him was a novel experience. Last spring he removed two small ovarian tumors, and a third one about the size of the uterus, at the sixth month of pregnancy. In other respects the pelvic organs seemed normal, and the operation was simple. Convalescence was natural until about the fourteenth day, when examination revealed a mass in the neighborhood of the larger pedicle. It was thought a purgative would probably cause the supposed exudate to disappear, but instead it increased until it filled the entire cavity from the umbilicus down, except a narrow strip on the right side. Dr. Polk still supposed the infiltration would disappear, possibly with the formation of an abscess, but incomplete intestinal obstruction developed, and on opening the abdomen he found the sigmoid flexure occupying a position at the brim of the pelvis, the parietal peritoneum thickened everywhere about half to three-quarters of an inch. During the manipulation he accidentally opened into the gut and bladder. The pedicles of the tumors were normal. The wounds were closed. On leaving the hospital he met Dr. Bangs, whom he asked what was wrong with the woman, and he replied that she had tertiary syphilis. She was put on iodide of potash, and lately on visiting his office was found to have no pelvic infiltration and to be quite well.

The theory of mycosis, suggested by Dr. Weir, appeared to Dr. Draper more reasonable than that of syphilitic gumma in explanation of the tumor. Dr. Polk said no microscopic or bacteriological examination had been made.

Abscess of the Liver.—Dr. Polk mentioned a case of abscess of the liver, with inflammatory obliteration of the gall-bladder, which he had operated upon three days ago by the open method, employing gauze drainage. It illustrated, he said, the innocuousness of the open method of treating hepatic abscess.

An Epidemic of Poliomyelitis.—Dr. C. L. Dana, in presenting a microscopical section, referred briefly to an epidemic of poliomyelitis, affecting children chiefly, which occurred last summer in a section of Vermont about thirty miles long by ten broad. For particulars he was indebted to Dr. Caverly, health officer of Rutland, Vt., who stated that in this limited population there had been as many as one hundred and fifty cases of typical poliomyelitis anterior during the months of June, July, and August. None of the children who were affected died, but a few adults did. No autopsies were obtained in man. Dr. Caverly had sent the speaker a hen which was paralyzed, and which had been one of a flock of hens with several cases of paraplegia coming on rather suddenly. The flock was at the end of a village where there had been fifteen to twenty-five cases of anterior poliomyelitis among children. Dr. Dana and Dr. G. M. Hammond studied the case carefully and found that the hen had bilateral motor paralysis of the legs, slight motor paralysis of the wings, none at all of the head and neck; there was no sensory trouble, no anæsthesia. After killing the hen, Dr. Dunham, of the Carnegie Laboratory, made careful biological study of one sciatic nerve and of the spinal cord, but with negative results, except that he obtained one culture from the sciatic nerve which he believed was accidental. There was no meningitis. On microscopic examination Dr. Dana found plain evidence of poliomyelitis in the lumbar enlargement, the appearance being very much like that which had been found in some specimens taken from cases of anterior poliomyelitis in the human adult. There was intense congestion and some hæmatin in the anterior horns.

He thought the occurrence was somewhat confirmatory of the view that anterior poliomyelitis was an infectious disease and might become epidemic. The other epidemics had been reported in literature. Only about ten per cent. of the cases occurred in adults. As to horses being affected, Dr. Dana said this was probable. But it seemed veterinarians were not in the habit of distinguishing sharply between meningitis and some other conditions.

Stated Meeting, December 7, 1894.

H. F. Walker, M.D., President, in the Chair.

Chronic Bilateral Parotitis.—Dr. Robert Abbe again presented the man first shown at the April meeting, with a swelling beneath and in front of the lobe of each ear. It had persisted for eighteen months, increased in size whenever the patient took a cold, was sometimes painful, and always very annoying because of its appearance. Dr. Abbe thought it was a bilateral parotitis, but said that Dr. Weir and Dr. McBurney were inclined to regard the case as one of symmetrical lipoma.

Dr. Weir, being present, again expressed his impression that the case was one of symmetrical lipoma, and Dr. Shrady concurred in this opinion and said he thought there would be no difficulty in extirpating the tumors.

Dr. Robinson thought there was reasonable doubt with regard to the diagnosis. Personally he thought there was something more than a mere neurosis. All sorts of medication had been tried for anæmia, malaria, hysteria, etc., but without benefit, and treatment directed against middle-ear trouble had only aggravated the symptoms. Iodide of potassium had also been given without benefit. When Dr. Starr and Dr. Fisher examined the patient there seemed to have been no ocular trouble, but Dr. Seabrook's examination had been made later, and, taken in connection with Dr. Dench's, led the speaker to the opinion that there was a cerebral tumor or pachymeningitis. There seemed also to be some word-deafness.

Dr. C. L. Dana said that with only a cursory examination of the patient presented, he was unable to confirm or deny the diagnosis made by Drs. Starr and Fisher. He was inclined to think the evidence presented by Dr. Robinson pointed to more than a functional trouble. Still, neurasthenic, hysterical, anæmic women sometimes suffered from headache, neuralgia, and tinnitus for years, and showed no organic lesion.

Perforating Typhoid Ulcer; Laparotomy; Recovery.—Dr. Robert Abbe reported the case (see page 1).

Dr. W. M. Polk congratulated Dr. Abbe on the happy termination of his case. He thought that with the kind of lymph exudate referred to, the chances of recovery were always better. Stress had very properly been laid upon the open method of treatment. He inquired whether it had been practised in the cases quoted, or whether the abdomen had been closed.

Dr. Abbe said that in the very successful case of Hook the abdomen was closed, but drainage was made through the pelvis below. In the three cases in England the perforated gut was stitched to the abdominal wound and the latter was closed up to that point. Dr. Abbe left the abdominal wound quite open in his case, simply closing that in the gut by the quickest way possible, dropping it back, and tamponading with gauze. Rapid closure took place, as usual, under this method.

Dr. Delafield: I understood there was leakage of fecal matter after the operation.

Dr. Abbe: That probably occurred from the action of calomel, but not until the third day. The fluid faeces flowed out on the peritoneum two or three weeks, but it did not disturb the patient.

Dr. Delafield: Then she had a fairly resisting peritoneum.

Dr. Abbe: But it was all blocked up by lymph.

Dr. Polk thought that stitching the coil of intestine to the abdominal wall would complicate recovery. In his experience it had done so, and he was of opinion that the open method was the ideal one for these cases. Of course recovery might take place by closing the abdomen, as in the case in Chicago, but he thought the chances were more in favor of recovery if the abdomen were left open.

Dr. Weir inquired what was the percentage of recoveries in cases of typhoid perforation without operation. In several of the cases which he had seen reported in the journals from time to time the fact was remarked upon as to the ease with which inflammatory thickenings in the gut could be recognized through the peritoneal coat. This might be of importance in detecting points of beginning perforation, and also in the surgical treatment of hemorrhage of typhoid fever.

Dr. George L. Peabody thought it well to bear in mind that the operations for perforating typhoid ulcer which gave a percentage of one recovery in six had been made upon select cases. The average case of perforation in typhoid fever, coming to the attention of the physician, would not, he thought, admit of any surgical procedure whatever. The patient was so near moribund that the mere suggestion of etherization would deter one from interfering. It would, therefore, be erroneous to infer from the percentage of recoveries thus far obtained from operative interference that the same ratio would be maintained if all cases were operated upon.

Regarding surgical treatment of typhoid hemorrhage, he must confess that he was positively against it, for he believed it would kill more patients than it would save. Many patients had hemorrhage and recovered with no other interference than, perhaps, the application of cold over the abdomen.

Dr. Bryant said he had had no experience with perforation due to typhoid fever, but he wished to express the opinion that the tamponade treatment of the abdominal wound was far the most successful under like circumstances. He would regard it as good luck on the part of an operator who might have recovery follow treatment by closing the abdominal wound.

Perforation Mistaken for Appendicitis.—Dr. Bryant related the case of a man who was brought to the hospital after having been suddenly seized with violent pain in the right side of the abdomen while walking the streets following a debauch. He had first been taken to a drug store, then to his home, and forty-eight hours after the accident entered the hospital. At this time he was in marked collapse. There was dulness over a tumor in the region of the appendix, and general tympanitic distention existed. The patient refused consent to an exploratory incision until four or five hours later. A large amount of pus and white, milky-looking fluid escaped from an incision into the tumor. The cavity was washed out, but nothing more was done, as further interference would have resulted fatally at once. A large drainage-tube and gauze were introduced. The interesting point in the case was revealed at the autopsy, when it was found that the trouble had arisen from a perforating ulcer in the duodenum, the size of a small lead-pencil. It was evident the leakage had run down to the region of the cæcum, and there had become hemmed in by inflammatory products, simulating appendical abscess. In the sac was found much of the milk and food taken into the stomach during life. It was a case, then, in which perforation was taken for appendicitis before and after admission to the hospital.

Dr. Weir remarked that he had seen three cases of perforation of the gall-bladder in which the extravasation had taken the course mentioned by Dr. Bryant, and formed a tumor in the position of a high appendical abscess.

A Bad Time for Operation.—Dr. V. P. Gibney queried whether the very fact that the patient had typhoid fever did not lessen the chances of recovery from an operation. At any rate, he had observed that children convalescent from the exanthemata, as scarlet fever and measles, withstood even simple operations poorly.

Dr. Abbe thought a weak heart-muscle was undoubtedly a bad element in the case, but one was in the face of death and was compelled to operate without regard to time.

Dr. A. H. Smith thought Dr. Abbe's case, and others he had cited, should lead us to hope that in hospitals, where the conditions for operating were perfect, and where no considerable time elapsed between the occurrence of symptoms of perforation and operation, many lives might be saved. To accomplish most it would seem necessary to have a standing order, requiring that the surgical staff should be notified at once when in typhoid cases symptoms of perforation arose, and it should be understood among the surgeons that such cases were legitimate ones for operation.

Dr. Robinson inquired of the surgeons whether they thought it would be best to operate immediately or to wait a while.

Dr. Polk thought that without doubt the patients would stand a better chance of recovery if the operation were done immediately, allowing for shock. Dr. Weir's suggestion was a good one, that in some cases an anæsthetic was not necessary, for often it was the anæsthetic that killed.

Dr. Geo. F. Shrady, after inquiring the time which had elapsed before the operation had been performed in the cases reported, went on to say that he regarded laparotomy as a perfectly feasible operation under the circumstances given in the paper, and he hoped it would become popular. There might be some difficulty in getting the sutures to hold, but he thought the quilted suture would probably prove reliable. Replying to an interrogatory by Dr. Robinson, he expressed the opinion that the earlier the operation was done after perforation and after the primary shock the better.

Dr. Delafield thought there could be no question but what, theoretically, the operation was justifiable, for most patients with perforation died if let alone. But he thought the statistics the author had quoted also showed that most patients died when operated upon. That was no reason, however, why they should not become better in the future. He had had some cases operated upon, and the one which seemed to him most favorable for interference had died. It was that of a boy, whose general condition was quite good, and the operation was performed twelve hours after perforation, but death occurred promptly.

Dr. Abbe made some concluding remarks. He said the question of recovery after perforation and without operation had been very thoroughly discussed. Although Murchison had seen seventeen cases recover under the opium treatment, scarcely any striking cases of recovery under this plan had been reported by others. Yet Dr. Abbe could see no reason why recovery should not take place occasionally by occlusion or walling in with lymph, especially where the opening was small and the escape of fluids limited. He certainly would not advocate operating during the early stage if shock were still present; but if it were possible to operate at all it should be done as soon as the patient had been calmed by opium, and there had perhaps been slight arrest by local action, such as probably usually took place almost immediately, although he felt personally that the patient should ordinarily be given time to recover from the

primary shock before interfering. He said Van Hook was of a different opinion. One case had been recorded in which death had taken place within ten minutes after perforation. Most patients lived several hours, but usually became so prostrated as to be beyond surgical relief within two or three hours. In his own case light adhesions had formed, hemming in the extravasation They broke at the end of forty-eight hours, the whole peritoneal cavity became infected with sticky, dirty-looking lymph, and had an operation not been performed at this stage death would certainly have resulted.

Dr. Delafield: But it would have been better to operate before the occurrence of general peritonitis; that is, as soon as the patient could bear it?

Dr. Abbe: Certainly. In reply to Dr. Peabody's suggestion that the cases saved by operation were probably select ones, and would not have died in any event, he said it was not so, for it was evident all would have died had they been let alone.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

MEETING OF THE MEDICAL COUNCIL—SIR R. QUAIN—DECREASE OF MEDICAL REGISTRATION IN IRELAND—PAY WARDS IN HOSPITALS—THE BURNING QUESTION—PROPOSAL TO BOYCOTT—CHELSEA HOSPITAL SCANDAL—CONGENITAL CYSTS SIMULATING ANEURISM—EXCESSIVELY RARE CASES OF SIGMOID DILATATION—LEUKÆMIA—A REAL THIRD TESTIS.

London, December 1, 1894.

The General Medical Council has been holding its fifty-seventh meeting. Sir R. Quain presided, and was warmly congratulated on his recovery from his illness. In his address he said he had not known in his thirty years' experience of the Council a session in which more important matters had to be considered. He spoke of the Swiss Medical Board having determined to reserve to themselves all the practice in health-resorts, and stigmatized such conduct as "selfish and all but heartless," and then hinted that English physicians would in turn remember where their patients could not obtain English advice. This is a fair warning to the Swiss, but does it not sound a little like an incitement to boycotting? I mention this because this method of action is just now occupying the chief attention of the profession—some expressing horror at such a thought as undignified, and even revolting, but a large number declaring they would practise it nearer home. It is curious, therefore, to observe the genial and venerable President setting, as it were, the example. His Irish blood is evidently not averse to the process—of course only in cases in which milder measures have failed.

Sir Richard also brought before the Council some statistics showing that a marked increase in the number of students and practitioners registered in Scotland has been going on for some years, with a corresponding decrease in Ireland. Why?

No little ill-feeling is being excited by the intention of the Great Northern Central Hospital to open pay wards, and the consulting staff may yet have reason to repent their decision to attend the pay wards gratuitously. The meeting of general practitioners in the district was most decisive as to their opinion on this departure, but the managers of the hospital will not budge and the staff ignominiously continue in office. A defence has been issued — courteously enough worded, but quite inadequate; a further meeting is to be held, but it will probably be as futile as the last. Meantime the word "boycott" has not only been muttered in tones of muffled anger, but sounded in loud defiance. A considerable number of practitioners declare they will no longer call in consultation any of the staff who attend in the pay wards. A little "high-falutin" nonsense is circulated in reply. The malcontents are gravely assured that they are bound to call in those likely to give the best advice, and therefore they must continue to act as heretofore in the matter. As if the staff of the offending hospital could not be matched in London! Weak indeed must be the cause in which such a plea is offered. Is it not a recognized thing to ostracize the physician who infringes the recognized code of ethics? But according to the apologists of the weak-kneed staff, those who had previously called in consultation men who had egregiously failed to maintain professional ethics must still recommend these erring consultants. The apology is too clumsy. It is said that the managers are determined to carry out their scheme, and that if the staff all resign others will be ready to take their places. No doubt! It has usually been so—shame to the want of professional union. The most flagrant modern cases was that of the Throat Hospital. When the staff retired *en bloc* from that mismanaged institution, others were appointed on the same day, and some certainly without special qualifications. But the staff in that case retired undeterred by a knowledge of what the result would be, and everyone (except the *British Medical Journal*) recognized that they had done their duty. If the staff of this Northern Hospital still hold office it is pretty clear they must face the determination of most local practitioners to ostracize them. If they retire and others "jump into their shoes," the same measure will doubtless be meeted out. Many are piteously bewailing the prospect of "boycotting being introduced into our noble profession." I am not sure that this drastic measure may not now and again be a most valuable means of purifying "our noble profession." At any rate the Northern suburb seems about to set the example.

The special meeting of governors of the Chelsea Hospital for Women came off on Wednesday, and although numerously attended lamentably failed in its duties. A cut-and-dried list of a new board of management was submitted, and after a feeble protest all were elected. The new board is very much of the old one—reinforced indeed by two or three outsiders who will be unable to resist the experienced members. It would be interesting to learn who is responsible for this list. The new staff have resigned and offer themselves to this same board for re-election. The whole procedure seems farcical, but is also a sad illustration of how hospitals are governed in London.

At the last meeting of the Clinical Society of London, on Friday, November 23d, Mr. Golding Bird related a case of an adult with a congenital cyst of the neck in the superior carotid triangle, in which there was both antero-posterior and lateral pulsation, and which, except bruit, gave the usual clinical characteristics of an aneurism. After describing the particularly flaccid state of the tumor, he expressed the opinion that lateral as well as forward pulsation of a cyst lying over an artery, but unconnected with it, could only occur when either the flaccidity of the cyst permitted it to mould itself round the artery, or when (which amounted to the same thing) the artery, with powerful pulsation, was large enough to compress itself deeply into the contour of the cyst; inflammatory cysts, *e.g.*, abscesses, near arteries being strongly walled enough to resist the impress of the artery.

Mr. Hulke remarked on the difficulty of diagnosis occasioned by its expansile pulsation. The character of its epithelial lining, and of its oily, fluid contents, left no doubt of its congenital dermoid nature. In its high and lateral position in the neck this cyst resembled certain congenital cysts of the neck, some of which have been found to be prolonged between the external and internal carotid arteries toward the pharynx. These

cysts and dermoids probably originate in partial closure of a bronchial cleft.

Dr. Sansom observed that the explanation given of the pulsation would also explain pulsating empyema.

Mr. Pearce Gould asked if after removal the carotid was really much exposed to view, sufficiently, in fact, to justify the suggestion that the growth wrapped round it. The lateral pulsation might be due to the flaccidity of the tumor, for if very tense no tumor could pulsate laterally, however intimate its contact with the artery.

Mr. Golding Bird, in reply, said the artery was really very much exposed after removal of the tumor, and Mr. Gould's remark was correct in the sense that a tense tumor could not be very well wrapped round an artery.

Dr. W. P. Herringham and Mr. W. Bruce Clarke, F.R.C.S., detailed a case of idiopathic dilatation of the sigmoid flexure in a gentleman, aged seventy-eight, who had for eight days obstruction of the bowels. The points to be settled were the cause and the site of the obstruction. There was a history of life-long constipation, which for the last six months had given place to regular action of the bowels. No stricture could be felt per rectum, nor any tumor in the abdomen, and there was no evidence of malignant disease. Attempts were made for two days to relieve the obstruction by purges and enemata, the patient's condition seeming to allow of this delay, and a similar previous attack having been thus cured. On the third day it was necessary to operate, when fæces were found in the peritoneal cavity, and the patient died a few hours later. The disease was found to consist in an enormous dilatation of the sigmoid flexure, which covered almost all the front of the abdomen. The inner surface was extensively ulcerated. In several places it was black and gangrenous, and in more than one had given way, allowing extravasation into the peritoneal cavity. There were old adhesions to the liver and to the omentum and recent peritonitis. There was no stricture, nor could any mechanical cause be discovered for the dilatation, which the old adhesions showed to have been of long standing. The intestine above and below the sigmoid was natural. Only eleven similar cases are recorded. Of these three were in elderly men : the other eight patients were much younger, and a much greater length of bowel affected. In one case impaction was found, but not sufficient in the others.

Dr. Angel Money suggested that in the case reported by him the distention was due to kinking of the sigmoid flexure. For the younger cases, Dr. Gee's opinion that mere constipation and retention of wind are the cause of the dilatation, seems borne out by Osler's description of a baby long under treatment.

Mr. Croft asked as to the pathological condition of the walls of the distended portion, whether it was due to thickening of a muscular character or to the deposit of organized inflammatory products. If to the former it could not be dependent on a paralytic condition. He asked in conclusion whether there was anything in the upper part of the rectum to lead the author to think that the sigmoid flexure had been kinked ?

In reply to questions, Mr. Bruce Clarke said his impression was that the sigmoid flexure had been kinked, probably on account of some obstruction due to fecal accumulation. Once that was set up each condition would aggravate the other. The operation he had performed was left inguinal colotomy, and Mr. Herringham said the hypertrophy was muscular, and he had instanced this as evidence against paralysis.

Dr. Frederick Taylor read a case of splenic leukæmia greatly improved by inhalations of oxygen and the use of arsenic, in a policeman, aged twenty-five, who had been losing strength and color for about a year. On admission he presented the characteristic features of a case of splenic leukæmia. He was ordered five minims of liq. arsenicalis three times a day, and thirty litres of oxygen by inhalation daily. The dose of liq. arsenicalis was increased by two minims every four or five days, until it reached forty-five on November 27th : the red corpuscles rapidly increased, the leucocytes fell, and a decided diminution in the size of the spleen was noted. Dr. Taylor stated that he had never before in a case of leukæmia seen such rapid improvement, both as regards the leucocytes and spleen, from any treatment as occurred in this case, though it must be admitted that he is not cured.

Dr. Coupland was unable to see how the inhalation of oxygen could have an effect in such a disease as this, especially if there were few red blood-corpuscles to convey the gas to the tissues. He could conceive of its doing some good when the corpuscles were laden with carbonic acid gas.

Mr. W. G. Spencer asked whether any increase in frequency or amplitude of the respiratory movements had been noticed as the result of inhalation. If so, this would of itself tend to stimulate the venous circulation and thus to lessen any concomitant congestion of the spleen.

Dr. Bradford thought the reduction in size of the spleen was due more to the arsenic than to the oxygen, because this had frequently been observed to follow arsenical treatment alone. Although in emphysema or pneumonia it was possible that inhalations of oxygen might be of service, he could not see how this could be the case in such a disease as leucocythæmia.

Dr. Herringham remarked that cases of leucocythæmia improved by themselves, and he referred to a case in the Middlesex Hospital, eight or nine years ago, the patient at present presenting no signs of having had the disease.

Dr. Hale White mentioned the case of a man who was at Guy's Hospital eighteen months ago for leucocythæmia, where he was given arsenic with benefit. The patient on leaving the hospital had ceased to take arsenic, but had nevertheless continued in excellent health.

A boy, fifteen years of age, was exhibited, from whom Mr. A. Lane had removed a supernumerary testicle. Such cases are rare, and the President, Mr. Hulke, remarked that he had not met one. Those recorded by old writers were probably encysted hydroceles of the cord. An analogy with this case was double kidney, each with its own ureter, an example of which he had met with.

THE COMMISSION BUSINESS.

To the Editor of the Medical Record.

Sir : In attempting to solve the problem of the doctors who give and receive commissions, it seems to me the difficulty lies partly in a failure to give fair weight to the business side of the practice of medicine, and in confusing with an actual consultation the simple referring of a patient to another, be it physician, hospital, or druggist.

As long as the community or individual derives benefit from the services of the physician, so long is he entitled to a return for his work, and it is certainly both just and reasonable to use business methods in business matters.

An actual consultation is one in which two or more physicians confer or act together in making a diagnosis, or in determining or applying treatment. This is, I think, the sense in which the term consultation is generally understood, and to which it should be restricted. The simple referring a patient to another physician, a hospital, instrument-maker, or druggist, is not in any sense a consultation. In the first instance, each of the consultants is entitled to his share of the fee ; in the second, the physician must collect his fee for advice in the usual manner, and is in no way entitled to any additional payment. This definition being accepted, it is simply a matter of method as to how

the consultation fee shall be collected. Now, for reasons well known to all, the attending physician is rarely paid in a consultation with an expert. One reason for this, it seems to me, is, that the patient regards the necessity for consultation as a confession of ignorance or lack of skill, and hardly cares to pay for what he thinks he does not get. At the same time, none will deny that frequently the duties of the physician in charge are most onerous, and that his knowledge of the case is of material aid to the expert.

Suppose for the sake of illustration the case of an operation done at the patient's home. The time is made to suit, if possible, the consultant, the attending physician sacrifices at least half a day in making necessary arrangements, any extra call, of whatever nature (likely his best patient), is referred to his competitor across the way; if the result is unfavorable his reputation must bear the brunt; the long, tedious after-treatment is charged at half price and paid at less.

The plan I would propose to remedy this injustice, and at the same time cure the commission business, is for the National or State Societies to provide a standard ratio of a joint fee to be charged and so divided in all actual consultations between general physicians and experts. This would do no injustice to the patient, and would secure justice to the attending physician; it would checkmate the wrong in the commission business, *i.e.*, the bidding for patients by the unscrupulous; the slight sacrifice on the part of the expert would be more than balanced by more frequent consultations and a more friendly feeling.

The practical working of the plan proposed is so evident that any illustration is almost superfluous, but to avoid any possible misunderstanding I will say that whenever a consultation is held or an operation done, the consulting physicians should determine on a total fee according to the circumstances, and then divide it according to a standard previously agreed to, or, if the suggestion here offered is adopted, as determined by the National or State Societies. The division should be as liberal toward the attending physician as possible, at least twenty-five per cent.

Much more might be said in favor of the plan offered, but the above simple statement of facts has cleared up the difficulty for me, and if I see it aright, it needs no bolstering.

Hamilton Mailly, M.D.

Bridgeton, N. J.

VAGINAL HYSTERECTOMY BY ENUCLEATION.

To the Editor of the Medical Record.

Sir: Will you kindly allow me to correct a mistake that I note in your issue of December 1, 1894? In a paper bearing the title, "Vaginal Hysterectomy by Enucleation without Ligature or Clamp," the author, J. Riddle Goffe, M.D., expresses the belief that the operation he records, and which was performed October 12, 1894, is the first operation of the kind ever done in New York. Now this statement is misleading if more weight is attached to it than an individual opinion usually commands. As a private belief it records the depths to which current medical literature has been investigated, and is an index of the author's familiarity with what his colleagues are doing. But facts and dates are strange things, and in their face even "I believe" cannot stand.

The truth is, this operation of uterine enucleation, which Dr. Goffe describes with all the detail and enthusiasm of the explorer who fondly believes that he is on ground which others know not of, or are too timid to tread, has been performed many times in New York, both before, and since, October 12, 1894. Speaking from my own experience alone, the operation, with certain modifications, has been a favorite one with me for fully two years, and during the past twelve months all of my vaginal hysterectomies, some thirty-five in number, have been performed in accordance with this principle of enucleation. The modifications of which I speak relate chiefly to securing the broad ligaments, with the object of thus building a floor for the pelvis, and giving additional support to the bladder.

Dr. Goffe seems to have adopted a very similar technique, though I do not wish to suggest that he has followed my practice, of which it would appear he was ignorant, else his "belief" would have shown as much familiarity with modern medical literature as with the writings of Chelius, to whom he credits the operation of uterine enucleation.

Permit me in closing to quote from a paper which I read before the New York State Homœopathic Medical Society, September 26, 1894, and which was published in the *New York Medical Times* for October, entitled "Vaginal Hystero-oöphorectomy for other than Malignant Diseases of the Uterus and Adnexa:" "If the clipping is done close to the uterus, no ligatures will be required on the uterine arteries, for up to this point there need be no hemorrhage to speak of, save possibly from the posterior vaginal artery, and that can be controlled by a running catgut suture, holding together the parietal peritoneum and vaginal wall. My dissection has now reached the ovarian arteries and the Fallopian tubes as they lie between the folds of the broad ligaments; and the uterus hangs suspended in the pelvis by these structures. While it is perfectly possible to remove the entire uterus by continuing this same separation of peritoneal covering and vascular net-work, making the operation practically a bloodless one, I prefer at this stage to lay aside the scissors and to ligate both pedicles, for such we may now regard the parts that hold the uterus, with strong catgut encircling ligatures, leaving one end of each ligature hanging from the vagina. The uterus is then cut out with the scissors. The next step will illustrate my reason for tying the ovarian arteries and Fallopian tubes, and for not continuing the process of dissection with which I began the operation. After assuring myself that there is no hernia of pelvic viscera in the vagina, I draw together and tie the two ligatures already placed, and by so doing approximate and unite the severed broad ligament, each fragment of which contains what remains of its Fallopian tube, the ovary, and ovarian artery. It will thus be seen that at one step, without the loss of time and without the difficulties attendant upon picking up and sewing together the peritoneum, I am able to close the pelvic outlet and to build a strong resisting wall against pressure from above and prolapsus of the bladder."

Truly yours,

Homer I. Ostrom, M.D.

42 West Forty-eighth Street.

"PREMATURE DELIVERY OF DEAD CHILD INDUCED BY ACUTE APPENDICITIS."

To the Editor of the Medical Record.

Sir: My present communication, as it will subsequently appear, bears important reference to Dr. Mundé's article entitled, "Premature Delivery of a Dead Child induced by Acute Appendicitis," which appeared in the Medical Record of December 1st.

If you will allow a slight modification of Walter Scott's phrase, I will say of the doctor as the poet said of his hero: "One blast upon his bugle-horn is worth a thousand women." The warning note of this eminent gynecologist will, if heeded, save the life of many a pregnant woman. And since after the publication of that highly interesting article, if a practitioner should be called to a pregnant woman with pain in the right iliac fossa, tenderness over the abdomen, and an unaccountable temperature, "and would not at once think of appendicitis," I would, with Dr. Shrady, stamp him "as one who does not take a medical journal," nor

ever attends his "medical society." However, the history of medicine, like the history of any other science, or art, or men, teaches one important lesson, namely: the great lead, all the rest, in the long run, follow, and patient humanity at first prayerful, but after thankful.

It is my high privilege, in this brief note, to put on record a similar case to that reported by Dr. Mundé; and adopting to some extent the doctor's phraseology, I should style my case: Abortion induced by acute appendicitis.

Although my case dates back many months, yet its merit did not impress me until I read Dr. Mundé's article, and his special emphasis on the "rarity of the occurrence."

Dr. Mundé it was who verified my diagnosis on the table, and he it is now who, in answer to a letter addressed to him, encouraged me to write up the case.

As my letter to Dr. Mundé embodies the history of my case, I shall ask the Editor to kindly print it in full.

December 1, 1894.

Dear Doctor: If you will pardon the presumption, I will call your attention to a slight oversight in your very instructive article in the Medical Record of above date.

You say: "So far as I am aware, there is no case on record of appendicitis during pregnancy." Now, I am witness to the fact that you have operated on a woman, in the Mount Sinai Hospital, for appendicitis post abortion; the inflammation of the appendix, however, began before the abortion occurred. I cannot recall the patient's name, nor the exact time I sent her to the hospital. She was on my "district" service.

The history was as follows: About the ninth week, when the woman thought herself pregnant, she began to feel pain in the right iliac region—a history of long constipation preceded this. The pain continued for three days, when she "miscarried." The miscarriage afforded her relief for one day. Thereafter, the pain continued in the same region with increasing severity. I saw the patient for the hospital eight days after the abortion, and eleven days after the appearance of the first pain in the right iliac fossa. At that time she was treated by two physicians for acute pelvic peritonitis following the abortion.

At my second examination I communicated my diagnosis of appendicitis to Mr. Minzesheimer (Superintendent of Mount Sinai Hospital), and had her at once admitted. You operated on her in the evening of the day she was accepted. You found a big appendical abscess, ill-smelling pus, gangrenous appendix, and agglutinated intestines. The case was a desperate one and the result was fatal. The case made a deep impression on me from the peculiar, yet agreeable, manner you complimented me on my diagnosis. (The compliment must remain a secret. . . .)

The importance of this case dawned on me only while I was reading your article, seeing the stress you laid on "the rarity of the occurrence." The history of the case is strictly accurate, as my recollection of it is very vivid.

To day, December 10th, I received a reply from Dr. Mundé, in which he says: "Thanks for your letter. I had hoped to meet you last Wednesday to tell you that I had quite forgotten the case you refer to, or I should certainly have mentioned it, and have given you due credit. Why do you not send a letter to the Medical Record embodying the facts? Both of us, and others, will probably hereafter bear this and the other case in mind under similar circumstances."

So far, then, we have two well-established cases of acute appendicitis occurring during pregnancy.

I would be done with my letter, but for one statement in Dr. Mundé's article. He says: "I need scarcely say that the death of the child was due to the high temperature" (104° F.). The doctor then leaves us to infer that a high temperature in a pregnant woman, from any cause whatever, invariably means death to the child in utero. Now, since Dr. Mundé bases his assertion on the one case in question, I wish to cite a counter-case in which the temperature was much higher (106° to 107° F. in the axilla) and was kept up for a longer time, and yet the woman was naturally delivered of a living child and to all appearances at full term. Dr. Mundé may possibly recall that case, for he saw it with me in consultation. It was a case of acute articular rheumatism, characterized by hyperpyrexia and marked tympanites. I delivered the woman, two days subsequent to the consultation, of a bouncing boy. There was no trace of ill-health about the little fellow, although his mother died five days after delivery with a temperature of 109° F. Yours respectfully,

R. Abrahams, M.D.

156 Clinton Street, New York, December 10, 1894.

To the Editor of the Medical Record.

Sir: The article by Dr. Paul F. Mundé, in last week's issue of the Medical Record, on "Premature Delivery of a Dead Child, Induced by Acute Appendicitis," with remarks on appendicitis in women, induces me to send you the inclosed report of a somewhat similar case, which, if you deem it worthy, I shall be pleased to see appear in the Medical Record.

On July 14th I was called to see Mrs. S——, a multipara, who was in the fifth month of pregnancy. She stated that she had been very constipated, and on the 12th had taken "a large dose of pills" which purged her very hard and repeatedly. Soon after this she suffered some pain in the right side, and became feverish. On the 14th she had a chill, and the pain in the right side became very severe, and distributed over all parts of the abdomen. I found the abdomen tympanitic and very tender. Hot fomentations, opium, and sulphate of magnesia were ordered. On the 15th she seemed better, and a more thorough examination could be made. Some induration and much tenderness could be made out in the right iliac fossa. No fever. Until the evening of the 16th she seemed fairly comfortable. At this time she had a second chill and suffered great pain. Uterine contractions set in soon after, and continued through the night. Temperature rose up to 104° F. Abdomen excessively tender, and incessant spinach-green vomit.. The fœtus was delivered about 9 A.M. on 17th, and the placenta removed with some difficulty. Hot fomentations, opium, and sulphate of magnesia repeated. The graver symptoms subsided promptly, and it was deemed advisable to defer operation until the woman could recover from the shock of labor. On the 21st she had some fever and considerable pain, and operation was set for next day. On the 22d, with the assistance of Drs. T. Shaw and Getty, I opened the abscess freely, and after irrigation drained with iodoform gauze. The after-treatment did not differ from ordinary cases of appendical abscesses. Recovery was rapid and complete.

Archibald C. Harrison, M.D.

Meyersdale, Pa., December 8, 1894.

IS MALARIA A WATER-BORNE DISEASE?

To the Editor of the Medical Record.

Sir: I have read, with great interest, the late discussion in your most excellent journal, in regard to malarial infection from water. I write this to show that in my experience malarial disease has not been carried by water in one instance at least. This ship left New York December 26, 1893, for Rio de Janeiro, Brazil, and arrived at St. Lucia, West Indies, January 1, 1894. From that time until April 1st, the ship touched at only two places, Rio de Janeiro, Brazil, and Bahia, Brazil. No one was permitted to go on shore at either of these places and no drinking-water was allowed on board from shore. The drinking-water was all dis-

tilled on board and was rarely in the tanks more than a few days or a week before being used. It will be seen that it was a physical impossibility for it to absorb or contain malarial poison. But in a crew of five hundred and fifty men there were sixty-two cases of malarial fever; varying in intensity from a mild intermittent to a severe remittent. Respectfully yours,

E. KERSHNER,
Medical Inspector United States Navy; Fleet Surgeon, N. A. Station.

FLAG SHIP NEW YORK,
NAVY YARD, NEW YORK.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I have read with great interest the discussion on the sources of malarial infection. Permit me to give my personal experience in support of Dr. Daly's idea that malaria is a water-borne disease. A brother of mine lives along the Jersey coast where malaria is prevalent. He used to suffer from an attack every year; also other members of his family suffered. I lived with him four years and never had an attack. The reason was I am in the habit of drinking boiled water, never cold. After I had convinced them that the water had some connection with the disease, and had insisted upon their using boiled water, they have been free from the disease for the last five years. It is very possible, as Dr. Jones points out (MEDICAL RECORD, December 1st), that the malarial germs may be disseminated by every agency that circulates, but I am positive that water is one of them.

320 EAST SEVENTY-EIGHTH STREET.

New Instruments.

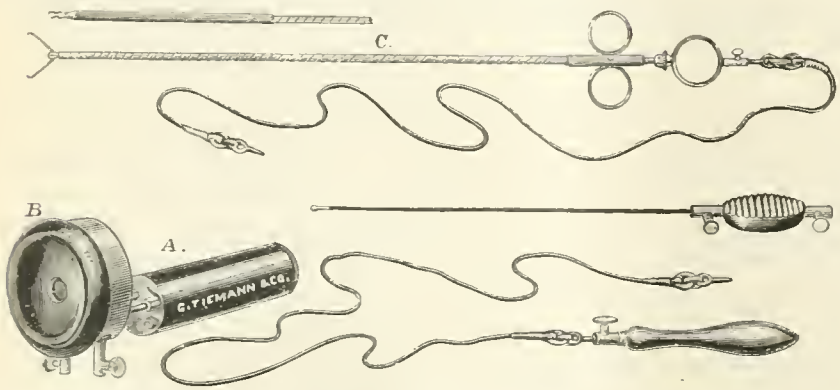
TELEPHONE BULLET-PROBE AND FORCEPS

BY H. M. WELLS, M.D.,

MEDICAL DIRECTOR UNITED STATES NAVY.

I DESIRE to call the attention of the profession to a telephone bullet-probe and forceps combined. In experimenting with Dr. J. H. Girdner's telephone bullet-probe I had great difficulty in hearing the ticking when the probe came in contact with the bullet.

Dr. Girdner considers the body of the patient to be a sufficient battery for this purpose, but repeated tests of his instrument, in the presence of several surgeons, convinced us that the current was not strong enough. I have, therefore, attached a one-cell dry battery in the form of a handle, A, to the receiver B, which can be detached when not in use, and which now responds almost as loud as an ordinary telephone and leaves no doubt about the contact of forceps and bullet. Instead of probing for the bullet, and, when detected, inserting the ordinary bullet forceps, which involves



more time, patience, and pain, I have combined the two instruments in one, so that the moment the bullet is struck and heard in the receiver it can be seized by the forceps and withdrawn.

The combined probe and forceps, C, is flexible, to follow the course of the bullet, and is insulated with thin rubber to prevent any particles of metal which, from any source, may be in the wound or tract, deceiving the ear at the receiver while searching for the bullet. These particles, if of sufficient size to be grasped, can be removed in the same way.

George Tiemann & Co., instrument-makers, have embodied these ideas in a complete, compact, and beautifully finished instrument, a single trial of which, I am convinced will give great satisfaction.

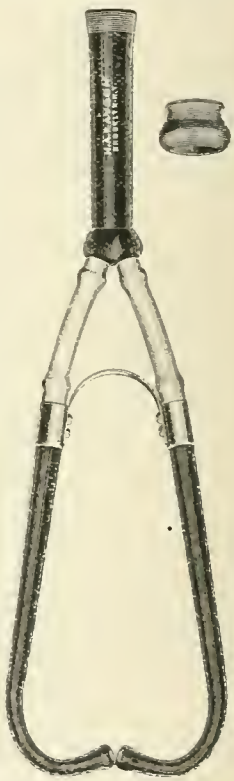
I do not wish to detract any merit from Dr. Girdner's most valuable application of the telephone to bullet-searching, I only desire to make it a little more practicable.

AN IMPROVED BINAURAL STETHOSCOPE AND IMPROVED SOFT-RUBBER BELL.

BY R. K. VALENTINE, M.D.,

BROOKLYN HOME FOR CONSUMPTIVES, BROOKLYN, N. Y.

THE description of this instrument was published for the first time in the New York MEDICAL RECORD, July 16, 1892, since which time improvements have been added.



The stethoscope is composed of hard rubber, the bell and ear-pieces are united by two sections of soft rubber tubing of superior quality, each about three and one-half inches long, and being perfectly flexible, the instrument is readily carried in the pocket. The bell consists of two parts, the lower of which is a tube four and one-half inches long, and having a bore of seven-eighths of an inch at its mouth, and five-eighths of an inch at the upper part, where it is screwed into the top section. This top section is five-eighths of an inch long, and has two canals, one-fourth of an inch in diameter, perforating the top and diverging as they pass upward. These two canals are separated at their origins only by a thin septum of hard rubber. The ear-pieces are perfectly straight up to the points where they are curved inward so as to enter the external ears. They have a bore of one-fourth of an inch at their lower extremities, and running upward the canals are cone-shaped and reduced to one-half of that diameter at the ear-tips. The ear-pieces are joined together by a simple flat steel spring.

The expense of making this stethoscope and its superior transmitting qualities are largely due to the perfectly smooth internal finish of all the hard-rubber parts. With the instrument in use the waves of sound pass upward through the long bell, are divided at the top by the sharp rubber septum separating the canals mentioned, and the divided sound-waves are transmitted in two straight lines to the curves which lead them directly into the ears of the operator.

Recently a small, soft-rubber bell has been added, which, we think, is of some practical value. The diameter at the mouth is not greater than that of the hard-rubber bell, and thus covers the same circumscribed

space under examination. It is made of pure rubber and has a flexible edge, which readily adapts itself by slight pressure to uneven surfaces, such as we find in patients whose chests are greatly emaciated, and where the hard-rubber bell is consequently valueless. Again, it is serviceable, as pointed out to me by Professor James Tyson, on patients whose chests are very sensitive even to the light pressure of a hard bell. In order that the soft-rubber bell may be always at hand, we would suggest unscrewing the hard rubber bell from the top and sliding the soft one down upon it.

A simple method of comparing the transmitting power of stethoscopes is to place the ear-tips in position in the ears and the bell upon the face of a watch or a clock.

Mr. H. A. Kaysan, of 34 Bond Street, Brooklyn, N. Y., has taken the greatest pains to follow my every instruction in the manufacture of this stethoscope, and so successful has he been that I have given him a certificate to that effect, which he will send out with each instrument.

Medical Items.

Contageous Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending December 29, 1894.

	Cases.	Deaths
Tuberculosis	104	95
Typhoid fever	23	5
Scarlet fever	102	8
Cerebro-spinal meningitis	3	3
Measles	78	4
Diphtheria	198	39
Small-pox	5	1

The Journal of Medicine and Science is the title of a new medical monthly published at Portland, Me., and edited by Drs. E. E. Holt and J. A. Spaulding. It is the organ of the Maine Academy of Medicine.

The Medical Laws of Massachusetts.—It appears that the laws pertaining to the practice of medicine in Massachusetts provide, among other things, that doctors shall be classed as follows: Class A certificate includes all doctors who are graduates of a recognized medical school and can show diplomas. Class B certificate includes doctors who cannot show a diploma, but have been practising medicine for the past three consecutive years. Class B claims that Class A through influence, is favoring legislation against them in the pursuit of their business.

Hence they called a secret meeting to devise means to protect themselves; the doings of which the *Boston Journal* found out and published in two columns. There should, says the *Journal of Medicine*, ultimately be no class in medicine except first class, and this should include those who are thoroughly educated in the fundamental branches of medicine, are honest, and conduct themselves like the true gentleman at all times.

A Public Bulletin Regarding the Care of the Eyes.—The physicians of Dubuque have issued the following curious circular: "1. Glasses for the correction of visual defects are demanded for a variety of reasons, some of which pertain to the ordinary changes in the refractive media incident to advancing age or otherwise, and some of which are due to true disease of the eye which from the nature of the case are far more serious, requiring for their proper treatment the services of one properly equipped in that department. 2. We believe that the one intrusted with the care of so important an organ as the eye should understand not only the mechanical methods of adapting glasses to the common refractive errors, but also the far more important and intricate diseased conditions, for the proper appreciation of which a knowledge of anatomy and physiology and the principles of medicine are absolutely essential. 3. We have, as residents of our city, men who, in our opinion, are exceptionally well fitted, not only to recognize and correct the ordinary refractive errors, but also to diagnose and treat properly diseases of the eye. We think it due to the public not less than to these gentlemen to bear this testimony."

This seems to be designed to warn the public against opticians.

Experiments with Mosquitoes in Mississippi.—Mr. Howard Weed, of the Agricultural College, Mississippi, has had some success in the abatement of mosquitoes by the free use of kerosene upon tanks of water and in other positions which he mentions. He says (*Insect World*): "Wishing to demonstrate the effectiveness of the remedy which I had recommended, I took a large glass jar and filled it nearly full with water from one of the tanks, which was fairly alive with the mosquito larvæ. The jar contained several hundred of the larvæ and I took it to the college physician, poured a little kerosene into the jar, and asked him to please watch the effect. This was as expected, for within fifteen minutes all the larvæ were dead. Some of the tanks for fire purposes were in dark attics and relatively free from larvæ. Four tanks had them in large numbers. Mr. Weed treated these with a gallon of kerosene, and ten days later the mosquitoes were nearly all gone from the campus and the collegians were able to dispense with the mosquito nets. Three weeks later some of the tanks were again dosed. Upon all the out-door tanks a thin film of kerosene has remained since the kerosene was put in. The campus is now nearly free from mosquitoes and has been so since ten days after the kerosene treatment. Hereafter during the summer, kerosene will be put in the out-door tanks, putting in enough to keep a thin film over the top of the water."

If Mr. Weed can successfully apply his methods to certain parts of New Jersey and Long Island, he will make countless hundreds smile and raise the price of real estate.

An Exhibition of Miraculous "Cures" has been taking place in Paris. Fifteen persons who declare that they were miraculously cured at Lourdes of terrible diseases presented themselves for inspection at a lecture given by Dr. Boissarie of the Bureau des Constatations at Lourdes. Dr. Boissarie's object was to refute various statements made by M. Zola in his book on Lourdes, and in order to prove that the cures which take place at the scene of Bernadette's visions are truly miraculous he brought from various parts of France fifteen persons healed within the last two or three years at Lourdes of diseases which medical science had pronounced incurable. Among these was the young woman, Marie Lemarchand, who figures in M. Zola's book as Elsie Rouquet. She went to Lourdes horribly disfigured with lupus, which had partly destroyed her nose and mouth and had spread over her whole face. Zola gives a realistic description of her appearance, which is anything but pleasant reading. It was, nevertheless, read at the meeting, and then Marie was asked to stand up and show her face. As she did so there was a general exclamation of wonder. The victim of lupus whom the doctors had abandoned had become again quite a pretty, fresh-faced country girl, whom medical men declared to be perfectly healthy. Another subject was a man who was pronounced at the Salpêtrière Hospital to be suffering from paralysis and blindness, caused by atrophy of the optic nerves. He went to Lourdes, and recovered his sight and health instantaneously. Then there was a girl who was cured of a cancer which was so bad that a surgeon refused to operate upon it, and another of a

wound in the foot caused by caries of the bone. This procession of "miraculés," and the medical diagnoses and certificates which were read, produced an extraordinary impression. The audience was largely composed of doctors and medical students.

One Hundred and Seven Intubations.—Dr. W. B. Pusey reports this number of intubations done for the relief of membranous laryngitis (*American Practitioner and News*, October 6, 1894). The ages of the children varied from under one year to nine years. The report was not of selected cases but included all those in which a tube was introduced, some few of the patients being almost moribund when operated upon. In no case where intubation failed was it believed that tracheotomy would have been of any avail. Of the 107 cases there were 48 recoveries, a little over 44.8 per cent.

The Blessedness of Beards.—It is to be feared that too many men deprive themselves of what Shakespeare calls "valour's excrement," without counting the possible cost. Whether the beard be an ornament to the masculine countenance we must, says the *British Medical Journal*, leave the ladies to decide; it certainly has its uses in hiding a weak chin, and in some cases it seems to be cultivated as a vicarious compensation for a hairless scalp. It is not, however, in its cosmetic so much as in its hygienic aspects that the blessedness of the beard—in which term we include the whole of the harvest usually claimed by the razor—is most apparent. That it is a safeguard to the throat is generally admitted, and writers of authority have insisted on its value as a protection against toothache and facial neuralgia. This is a goodly sum of advantages to the credit of the beard. Dr. Chabbert, of Toulouse, has, however, yet more to say in its favor. According to this practitioner the beard seems to be a very efficient defence against that form of facial paralysis which is caused by cold. This affection is far more common in women than in men, though the latter are, of course, much more exposed to the cause which produces it. When facial paralysis *a frigore* does occur in men, they are almost invariably individuals to whom Nature has been step-motherly in the matter of beard, or who have wantonly thrown away the protective covering with which she had clothed their faces. Dr. Chabbert cites the experience of several physicians, in addition to his own, in support of his opinion. Professor André, of Toulouse, has seen several cases of the affection in question in women, but not one in man; he has heard of one, indeed, which would appear to be an excellent example of the exception which proves the rule, for the patient was a "lyric artist," with the *faccia di musico* so distasteful to Lord Byron. Professor Pitres, of Bordeaux, has seen twelve cases in women and only two in men; both the latter shaved, though as one of them underwent that operation only twice a week, his case perhaps does not count for much unless it be held that his face was more vulnerable after these periodical denudations. Similar observations are quoted from Dr. Olivier, of Toulouse, and Dr. Sudre, of Carmaux. These facts, though hardly sufficient to found an induction on, seem, at least, to establish a *primâ facie* case for the utility of the beard against facial paralysis of the kind referred to. In these days, when man's traditional privileges are one by one being invaded by the "new woman," he may perhaps be forgiven for making the most of such advantages as may be considered exclusively his own.

The Historical Case of Diphtheria.—Shortly after Louis Bonaparte had taken up his residence in his new kingdom of Holland his eldest boy was seized with croup—most probably diphtheria—which proved fatal. Napoleon heard the news about a week before the battle of Friedland, and was so much affected by it, that he at once commanded that steps should be taken to offer a prize for the best essay on Croup, its Origin, Nature, and Treatment. The prize was 12,000 francs. Eighty-three essays were received. Dr. Cabanès has recently examined some of them, and declares that even the two which divided the prize display how extraordinary was the ignorance in those days of a disease which was certainly common, and well known to be fatal. Yet there were many good clinical observers in France at that date. Two results naturally followed the action of the great conqueror. In the first place nothing new was found out about croup; secondly, all the unsuccessful candidates were indignant. The son of Constant, Napoleon's valet, died of croup shortly after the award. Why, said the defeated essayists, were not the recommendations of the successful writers carried out by the physicians who awarded the prize?

Charcot's Pathological Museum.— Professor Raymond, Charcot's successor, in his opening lecture at the Salpêtrière, sketched the career of his distinguished predecessor and the development of his service at the Salpêtrière. Charcot felt a glow of pride when he announced to his pupils that his service could boast of an anatomo-pathological museum with a studio for taking casts and photographs of pathological specimens, limbs, etc. M. Raymond made a slight digression to tell his listeners that this laboratory, so vaunted by Charcot, was in reality only an ill-lighted narrow passage insufficient to meet the wants of the service. Dr. Raymond has, with the co-operation of the Dean of the Medical Faculty, the Director of the Public Assistance, and the Director of the Salpêtrière, succeeded in organizing a fresh laboratory, which does not realize his ideal, but nevertheless is spacious and well lighted. Dr. Raymond looks forward to the establishment of laboratories of applied psychology and therapeutics, and to the thorough reorganization of the laboratory of electrotherapy.

The Need of a Registration Law in Maine.—Every month brings to the observation of investigating physicians (says *The Journal of Medicine and Science*) some new insult to the State of Maine as well as to the medical profession in one way or another. The most recent case that has come to our notice, of medical quackery, is this: A few weeks ago a travelling "oculist" in the western part of the State, was permitted, in these advanced days of medicine and surgery, to advertise himself as an oculist who had studied in Europe and New York, and after fitting bad lenses on all whom he could dupe, to operate on a case of squint, with bad results, and to decamp with his fee before he could be punished. This injury to the patient and insult to the skilled specialists in Maine could not have been accomplished if there had been a law compelling all medical men to be registered before receiving permission to practise. More than this, and a greater disgrace to the community, the patient who suffered injury from such an operation done without aseptic surgery, was disinclined to trust her eyes to such a traveller as this, and only did so on the assurance of her clergyman that he was good. When the one man in the community whom one might expect to have some knowledge above the ordinary dweller in the country, falls so low as to recommend a travelling eye doctor, without any qualified residence, what can we expect from the man or woman of ordinary intelligence? Still another recent case is that of a travelling "oculist" from New York, who insisted on operating on both cataracts of a woman, without preliminary treatment, and without proper rules of modern surgery, and with the result of no recovery of vision in either eye. The fee for the operation collected, the wanderer departed for other scenes, and naturally his name is not in any New York directory. A registration law could have prevented this robbery not only of money, but of the chances of sight being restored by skilful treatment. But this is no better than the barber surgeon oculists of the sixteenth century.

THE TREATMENT OF DIPHTHERIA, INCLUDING SERUM THERAPY.

By H. W. BERG, M.D.,

ATTENDING PHYSICIAN TO THE WILLARD PARKER HOSPITAL, NEW YORK.

THE term diphtheria, up to a decade ago, had so vague a significance that even the best authorities were not agreed as to what clinical or pathological conditions were embraced under it. While some gave the name to all so-called croupous inflammations of mucous membranes with the production of pseudo-membrane, others limited the term to an acute infectious disease of a constitutional character with local, generally throat, lesions, the local lesion being generally characterized by the production of false membrane. The researches of Klebs,[1] Loeffler,[2] Prudden,[3] Roux [4] and Yersin, and a host of others, have taught us much more about the nature of diphtheria than is known about perhaps any other acute infectious disease. They have taught us that while clinically true diphtheria resembles other similar conditions embraced under the term of pseudo-diphtheria, the two groups of affections are radically different in their etiology viewed from a bacteriological stand-point.

Although the purpose of this paper is not to study the bacteriology of diphtheria, but rather its treatment, yet, in view of the light thrown upon the treatment of diphtheria by our knowledge of the bacteria which cause it, an apology for prefixing a *résumé* of the main points in the bacteriology of diphtheria to a paper on the treatment of the disease is hardly necessary. In 1883 Klebs first described a characteristic bacillus, which he had found in the false membrane in the throats of patients dying from epidemic diphtheria. In 1884 Loeffler carried these investigations much further, confirmed Klebs's discovery of a characteristic bacillus present in the pseudo-membrane of fatal epidemic diphtheria, and succeeding in isolating the Klebs bacilli from the bacteria accompanying it, obtained the bacillus in pure cultures. He was able to inoculate the abraded mucous membranes of the trachea of susceptible animals with pure cultures of this bacillus, and thus obtain the local manifestations of diphtheria and subsequent death; while the hypodermatic injection in guinea-pigs of a quantity of bouillon culture of the bacillus resulted in death with the customary lesions of diphtheria. Park describes these bacilli as varying in diameter from 0.3 to 0.8 μ., and in length from 1.5 to 6 μ. They occur singly and in pairs, and very infrequently in chains of three or four. The rods are straight or slightly curved, and usually are not uniformly cylindrical throughout their entire length, but are swollen at the ends, or pointed at the ends and swollen in the middle portion. Even from the same culture different bacilli differ greatly in their size and shape. The two bacilli of a pair may lie with their long diameter in the same axis, or at an obtuse or an acute angle. The bacilli possess no spores, but have in them highly refractile bodies. They stain readily with the ordinary aniline dyes, and retain their color after staining by Gram's method. With an alkaline solution of methyl blue, the bacilli, from blood-serum cultures, especially, and from other media less constantly, stain in an irregular and extremely characteristic way. The bacilli do not stain uniformly. Loeffler did find some cases of so-called diphtheria in which these bacilli were not present, and in the light of our present knowledge it would have been remarkable if every case examined had shown the characteristic bacilli. For cases of pseudo-diphtheria are not distinguishable clinically from true diphtheria, so that presumably some of the cases examined by Loeffler were cases of pseudo-diphtheria. In this way, too, we can account for so excellent an observer as Dr. Prudden being unable to confirm, in a series of fatal cases of diphtheria taken from New York hospitals, the results obtained by Loeffler. Most of Prudden's cases were diphtheria complicating scarlatina, which in most cases is only so-called streptococcus diphtheria. But in his second contribution to the study of this subject this same authority has confirmed the findings of Loeffler. It remained for our own city, however, to test the question of this constant occurrence of Loeffler bacilli in true diphtheria upon a scale hitherto unequalled. In 1893 the New York City Board of Health instituted a series of accurate bacteriological examinations of all cases of suspected diphtheria reported to the Board as occurring in the city of New York. This work was performed under the direction and supervision of Dr. Herman M. Biggs, by Dr. William H. Park and Mr. Alfred L. Beebe, and from the report of these latter gentlemen to Dr. Biggs [1] much interesting and valuable information concerning diphtheria that occurred from May 4, 1893, to May 4, 1894, can be gleaned. There were 5,611 cases of diphtheria reported and investigated bacteriologically, in which Loeffler bacilli were present in 3,255 of these, in 1,540 no Loeffler bacilli were found. Eight hundred and sixteen cases showed no Loeffler bacilli, but for many reasons; probably often through faults of technique in inoculating culture tubes, and for other reasons, the results of the investigations were unreliable. Excluding these cases then, about sixty-eight per cent. of the cases reliably observed were cases of true diphtheria, as shown by the presence of the characteristic bacillus, overwhelming evidence, even if no more were learned from these investigations, that the Loeffler bacillus is the active agent in the production of true diphtheria. The belief, then, that the Klebs-Loeffler bacillus is the specific infectious agent in diphtheria rests upon the following data:

1. It has been seen by every competent observer, and in enormous numbers of cases, at the site of the pseudo-membrane, both by cover-glass examination of the exudate, and by examination of cultures made by inoculating culture-tubes with the exudate.

2. This bacillus is found only in true diphtheria, or in diseases complicated by true diphtheria; although Park concludes, from a series of investigations, "that virulent diphtheria bacilli are to be found in the throats of a small proportion of healthy persons throughout the city, and that they have been derived either directly from diphtheria cases or from those who have been in contact with them."

3. Pure cultures of this bacillus induce characteristic diphtheritic inflammations when inoculated into certain of the lower animals, followed by local paralysis and other clinical manifestations of true diphtheria. Thus when such inoculations are made into the trachea of rabbits they cause membranous croup and tracheal pseudo-membrane, with œdema and swelling of the tissues and swelling of the glands of the neck.

Loeffler, Welch and Abbott,[1] and others have found that when susceptible animals are inoculated with pure cultures of the diphtheria bacillus, and diphtheria results, the bacilli are only found at the site of the inoculation. Cultures made from the blood of affected animals never showed bacilli. Martin, Behring, and Frosch, however, have found, although rarely, bacilli in the blood of animals thus affected.

It would thus appear that in true diphtheria we have an acute infectious disease with constitutional and local symptoms: the local inflammation is very generally characterized by the production of pseudo-membrane, in and about which Klebs-Loeffler bacilli are found. Sometimes, however, these bacilli are found in throats that show no sign of false membrane, but have simply a congestion and swelling of the mucous membrane, with more or less constitutional manifestations. Most observers agree. Park among others, in considering that the presence of the Loeffler bacilli, with inflammatory swelling of the mucous membrane, is sufficient to stamp these cases as true diphtheria, and that they should be so treated. The well-known constitutional symptoms frequently so great as to cause death from the severity of the septic manifestations, or in other cases well-known sequelæ due to a profound toxæmia of the nervous system, and to inflammatory changes in distal organs, logically render it absolutely necessary to suppose that since the pathogenic bacillus is only found locally at the site of the lesion in the mucous membrane, the constitutional symptoms are the result of some toxic agent produced by or under the influence of the bacillus, and spread throughout the system by the lymphatics and blood. Experimentally a bacillus which destroys the life of a susceptible animal when injected beneath the skin or mucous membrane, and which gives rise to severe constitutional symptoms at a distance from, although itself only present at, the point of injection, must owe its power to the production by its agency of a toxic material which is carried by the lymphatics and circulation to distant parts of the body.

In 1888 Roux and Yersin made observations tending to show the pathogenic power of cultures of Loeffler bacilli filtered through porous porcelain. In a later contribution to the study of this subject they showed that the reaction of recent cultures which had been filtered was acid, while old cultures similarly filtered had an alkaline reaction; the recent-filtered acid cultures were less harmful, comparatively, than old alkaline reacting cultures, when injected into animals. As to the chemical nature of the poison present in these filtered cultures of the true diphtheria bacillus Roux and Yersin believe that it is a diastase. The toxic power of this poison is very much reduced by exposure to a temperature lower than 58° C. for two hours, while subjection to a temperature of 100° C. for twenty minutes completely destroys it. This toxin is insoluble in alcohol, and can be precipitated by alcohol from old cultures. It appears to be an albuminoid substance, but its exact composition is unknown. We have, then, clinically, in true diphtheria, to treat a communicable infectious disease, which is characterized by a local lesion at the site of the Loeffler bacilli, and constitutional symptoms due to the pathogenic activity of a tox-albumin brought into existence by the influence of the bacilli. It will, therefore, be proper to discuss the treatment of the affection under the following heads:

[1] Bulletin of the Johns Hopkins Hospital, February and March, 1892

1. The prophylactic and preventive treatment, including the discussion of the conditions under which the disease is communicated from one to another.

2. The treatment of the local lesion.

3. The treatment of the constitutional effects of the pathogenic action of the toxin secreted by the Loeffler bacilli.[1]

Prophylactic Treatment.—In the prophylactic treatment of true diphtheria we have the advantage of knowing the pathogenic factor we have to combat, namely, the Loeffler bacillus. This bacterium, as I have already stated, is found for all practical purposes only at the site of the local lesion; in the vast majority of cases this is in the throat and upper air-passages. We find it most plentifully distributed in and about the pseudo-membrane. Shreds of this membrane are the fruitful nidus of the bacterium. Competing, however, with the false membrane in respect to a plentiful deposit, are all the discharges from the site of the pseudo-membrane, and even on the surface of mucous membranes in the neighborhood of the disease, not the site of pseudo-membrane, the Loeffler bacilli can be readily obtained by culture. In eighty per cent. of cases occurring in New York City, during the past year, of so-called croupous laryngitis, Loeffler bacilli have been found by simply swabbing the posterior wall of the pharynx. Thus the discharges from the nose, mouth, throat, and larynx of patients suffering from true diphtheria are highly infectious, and through them the disease is communicable. Not only is this the case, however, but the throats of those coming in contact with patients suffering from diphtheria have been found to contain Loeffler bacilli while in health. In some of these diphtheria developed later on; in others diphtheria did not develop in the affected individual, but contaminated other persons with true diphtheria. Park estimates that "virulent diphtheria bacilli were present in about one per cent. of the healthy throats in New York City at the time of these examinations (May, 1893, to May, 1894), and most of the persons in whose throats they existed had been in direct contact with cases of diphtheria." "The members of a household in which a case of diphtheria exists should be regarded as sources of danger, unless cultures from their throats show the absence of virulent diphtheria bacilli." As to the length of life of these bacilli after they have been discharged from the body, it is found that their virulence persists for a long time. Loeffler and Park found that the true diphtheria bacillus maintained its life upon blood-serum for seven months. Roux and Yersin found that they maintain their life in dried shreds of membrane for twenty weeks. Thus the dried sputum upon clothing, toys, and the like might infect five months after the clothing had been worn by a diphtheritic patient. In my own practice two severe cases of diphtheria had been treated late in spring, and on recovery the patients were sent away to the country. The sick-room was not again occupied until November; it had been in the meantime thoroughly fumigated. Two weeks after the return of the children to this room, a severe attack of membranous croup occurred in the youngest child, of which the little patient died.

A proper bacteriological examination is the most important factor in the prevention of diphtheria. The method of making a bacteriological examination of the discharges from a suspected case is as follows: A sterilized swab of cotton and tube containing sterile solidified blood-serum are the necessaries for making a culture. The swab is rubbed gently but firmly against the suspected mucous membrane if no exudate be visible, then immediately on removal inserted into the serum tube, and the wet portion of the swab rubbed gently and yet thoroughly upon the surface of the serum. Thus the culture tube is inoculated. This tube is then placed in an incubator, and kept at 37° C.

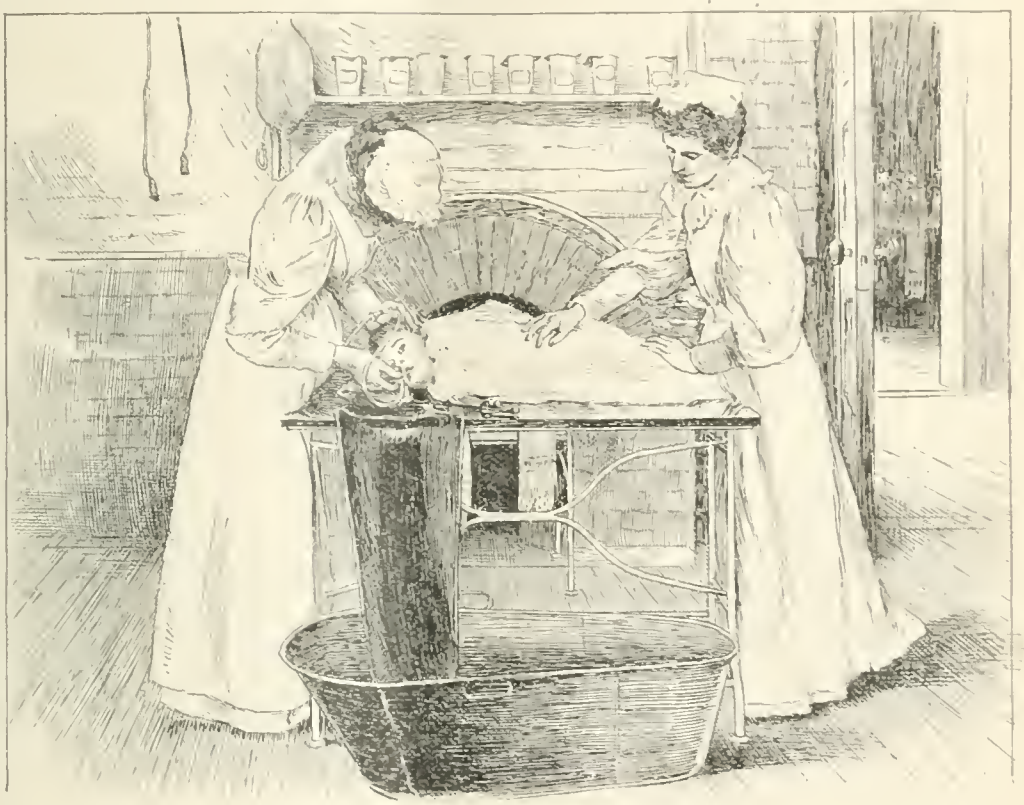
[1] Annales de l'Institut Pasteur, 1888.

for twelve hours. It is then ready for examination. A slide is then made for the microscope. A trace of water is placed upon a clean cover-glass; a sterilized platinum needle takes up a little of the surface of the culture medium where most of the colonies have grown; this needle-point is rubbed upon the drop of water on the cover-glass, until the bacteria are supposed to be evenly distributed upon it. The cover-glass is allowed to dry in the air. It is passed rapidly three times through the Bunsen flame, covered with a drop of Loeffler's solution of alkaline methyl blue, and allowed to dry for ten minutes. It is washed in clean water, dried, and mounted in balsam. It may be examined with $\frac{1}{12}$ immersion lens.

We find that the patient himself is the most fruitful source of contagion. Those who come in contact with the patient, including the nurses, relatives, and friends, and even the physician, are further agents for spreading the bacteria, and, thirdly, that the furniture, utensils, clothes, and even the walls themselves, become contaminated with shreds of membrane and discharges containing Loeffler bacilli, and that all of these may become sources of infection to those in health.

As to the question how long the patient is a source of contagion, that depends upon the length of time that the bacilli can be obtained by culture from diseased mucous membranes. The bacilli persist in most cases after the pseudo-membrane has disappeared. The length of time that they persist varies partly with the severity of the case, partly with local treatment adopted. Of 605 cases that recovered, Park and Beebe* found that in 304 the diphtheria bacilli disappeared within three days after the disappearance of the exudate; in 176 cases the bacilli lasted for seven days; in 64 cases, for twelve days; in 36 cases, for fifteen days; in 12 cases, twenty-one days; in 4 cases, twenty-eight days; in 4 cases, thirty-five days; and in 2 cases, sixty-three days after the disappearance of the exudate. In all of these convalescent cases the Loeffler bacilli, although growing gradually less numerous and becoming more admixed with cocci, are still virulent generally to the end. It becomes highly important as an element in prophylactic treatment to maintain the isolation of cases of true diphtheria as long as any Loeffler bacilli are found. Accordingly, at the Willard Parker Hospital the resident staff make cultures from the throats of convalescents at frequent, almost daily, intervals after the disappearance of the membrane, in order to discharge the patient as cured only when several days have elapsed without the finding of diphtheria bacilli in the cultures. Although this adds a great many days of hospital care to individual cases, it prevents the carrying of infection to healthy friends outside. It would be well if the laity could understand that a case of diphtheria should remain isolated until the absence of diphtheria bacilli in the throat has been proved.

Now as to the patient's friends, nurses, and physician looked upon as a source of contagion. It may be taken for granted that in everything the patient's clothes, skin, hair, fingers, mouth, etc., touch, there is a strong probability of some bacilli being caught, for the patient contaminates his own body, together with his surroundings with pseudo-membrane and discharges, which dry on his person and surroundings and are thus taken up by others. All the more is this true because the little people whom diphtheria has chosen for its own, are not old enough to be the subjects of active personal cleanliness. It follows, therefore, that those engaged in nursing the patient should be, as far as possible, isolated from other people. The physician above all people should guard himself from contamination, if not for his own sake for that of his *clientèle* and friends. At the Willard Parker Hospital it is the custom, before entering the diphtheria wards, for the physician to envelop himself in a muslin gown with a hood over his head. This gown has been previously sterilized by baking; it is long enough to reach almost down to the heels of the shoes—these latter are covered with ordinary rubbers. Thus clothed the physician enters the hospital ward. I have made it a rule in private practice, in lieu of the gown, to have plenty of towels to facilitate the handling of the patient. His body is not touched by my bare hand without the intervention of a clean towel; whether it be the head or the face or the wrist or chest of the patient that must be handled, it should always be with the intervention of a towel. A towel should be placed upon the chair upon which the doctor sits, and another one folded upon his lap. All instruments used for examining the throat and nose should be previously and afterward sterilized, and a solution of creolin or bichloride of mercury used to wash the hands immediately after leaving the apartment. As far as the friends are concerned, the best of all precautions is isolation. That this cannot be complete in the present state of society, and in consideration of the enormous frequency of the disease, goes without saying. But the nearer we approach the ideal



Irrigation of Naso-pharynx.

isolation, even with regard to mild cases of diphtheria, the less frequent will be the disease. It is not at all rare to find children suffering from true diphtheria, without constitutional symptoms and but little angina, sent to school, where they infect healthy children. To guard against this, children and adults complaining of the slightest throat-lesions should be isolated.

The room in which the patient lies should be isolated not only from the rest of the household, but measures should be taken to keep strangers from coming in contact with the apartment in which the patient is, and also with those engaged in waiting upon him. Above all things should cases of diphtheria be carefully isolated when they occur in the tenement districts, although perfect isolation is here practically impossible. It is needless to say that diphtheria occurring in living apartments, in connection with tenement-factories, candy-stores, butcher-shops, milk-shops, and bakeries is especially dangerous, owing to the broad channels of infection of the community which these occupations open.

A third source of infection is the fact that the furniture, utensils, clothes, and even the walls of the rooms, in fact all the surroundings of the patient, become contaminated with discharges and sputa containing Loeffler bacilli. Here the question arises how shall all these various objects be made free from the bacteria of diphtheria. Some articles cannot be so disinfected, and such should, if possible, be destroyed. The walls should be painted, old wall-paper should be removed and replaced by new; floors scrubbed with carbolized water in a one per cent. solution, or mercuric chloride solution of 1 to 4,000. All articles, such as bedding, blankets, mattresses, etc., should be subjected to dry heat at 100° C., in other words, baked. Steam at 100° C. will, of course, destroy all bacilli, but probably also the furniture. We are forced therefore to rely upon chemical bactericides, such as vapor of burning sulphur and chlorine gas.

As to the further question, now attracting so much attention, as to whether it is possible to render animals immune to the toxic products of the bacillus of true diphtheria, although properly belonging to the prophylactic treatment of diphtheria, it will be best to discuss this under the head of the antitoxin treatment, and thus avoid repetition of the same facts.

Treatment of the Local Manifestations of True Diphtheria.—The relative importance of the local as compared with the constitutional treatment of true diphtheria depends upon the site of the local manifestation, and to a certain extent the stage in which the case comes under treatment. It is evident, for instance, that in a case of diphtheritic croup, with threatening death from dyspnœa, due to occlusion of the larynx, the importance of relieving the stricture by intubation or tracheotomy for the time, overshadows the necessity of proper constitutional remedies to counteract the poison of the disease. Again, many observers believe, among them Loeffler himself, that if the site of the primary lodgement of the Loeffler bacilli is locally treated sufficiently early to destroy these before the toxic elements which they produce have affected the system, that systemic remedies become superfluous, so that under any circumstances the treatment of the primary local lesion of diphtheria is an extremely important one. A consideration of cases of diphtheria as they occur clinically will teach us that the local treatment has for its object: 1st, The removal of the toxalbumins which are the result of the activity of the Loeffler bacilli; 2d, the destruction of these bacilli; 3d, the hastening of the separation and expulsion of the false membrane, and 4th, the relief of fatal dyspnœa resulting from obstruction of the larynx and trachea by false membrane and other diphtheritic products.

Fortunately the usual location of the primary lesion of diphtheria, the throat and nose, is so easily inspected that a diagnosis of a commencing diphtheria can often be made early enough to render the local treatment an important factor in the cure of the disease. The remedies and their mode of application will depend to a certain extent upon the situation of the pseudo-membrane; thus toxic products, bacilli, and false membrane situated in the larynx cannot be attacked by fluid solutions, but rather, if at all, by vaporized remedial agents, such as calomel fumigation or turpentine inhalation, for instance, while the pharynx, tonsils, buccal and nasal cavities are open to treatment with solid or fluid agents. It would be futile to discuss all the methods and agents used in the local treatment of pharyngeal and nasal diphtheria, and I shall mention only those procedures which I have found effective both in private and hospital practice. In the first place the washing away of the toxic agents, the false membrane, and other diphtheritic products can be best accomplished by the mechanical action of fluid solutions. In these solutions we may dissolve agents that are more or less germicidal, such as the bichloride of mercury, boracic acid, carbolic acid, peroxide of hydrogen, salt, etc. The ideal solution will be that one which can be used in quantities sufficiently large to clean and wash off all of the deposits that cover the mucous membrane without being too adherent to it, and without injury to the mucous membrane or to the system if swallowed; such an ideal solution should, furthermore, if possible, have the power of destroying the Loeffler bacilli and its toxic products. It is evident that an ordinary bland, neutral salt solution, at a temperature of 85° F. can be used in unlimited quantities until all the loose diphtheritic products have been washed away; such a solution, however, has no germicidal properties. There are those who do not believe that anything is gained by the germicidal action of the solution used for douching the throat and nose of these patients. Thus a great many cases are treated in the Willard Parker Hospital locally by irrigation of neutral salt solutions with very good results. To test the question of the advisability of using antiseptic and germicidal agents in the irrigating solutions for the throat and nose, at the Willard Parker Hospital, a series of cases were subjected to local irrigation with warm salt solutions every one to three hours; a second series were subjected to this treatment, and, in addition, were sprayed every three hours with peroxide of hydrogen, in the shape of pyrozone, recommended by Dr. Northrup, varying in strength from five to twenty-five per cent., according to the severity of the case, and a third series of cases were subjected to irrigation by a 1 to 3,000 or 4,000 solution of the bichloride of mercury.

It was found that while the average number of days in which membrane persisted in the throats of those treated by salt-water irrigation was only six to nine days, that under bichloride irrigation the average duration was seven to nine days, while with salt water and pyrozone it was nine to sixteen days. The bacilli, however, persisted in the salt-water cases for 10.2 days, while in the bichloride cases they disappeared 7.4 days after the disappearance of the membrane, and in the pyrozone and salt-water cases 9.6 days. It would appear, therefore, that a mechanical washing away of the diphtheritic products is best accomplished by the warm salt-water irrigation, probably because being harmless it can be used in much larger quantities than a germicidal solution such as the mercurial sublimate; but the bacilli, and probably what is more important, the toxic products, disappear most rapidly under a bland germicide like corrosive sublimate, or in my experience what is equally good, a solution of boracic acid, 1 to 30, or a tablespoonful to a pint of water. The latter solution I use without salt water, it being sufficiently mild to use in large quantities. If the mercuric bichloride is preferred on account of its stronger germicidal action the salt solution should be used for the mechanical work of thoroughly irrigating the throat and nose, and

this should be followed by the solution of mercuric bichloride. Of course when the latter is used, should symptoms of mercurial poisoning occur, which I saw once at the Willard Parker Hospital during the summer, then the bichloride should be stopped and the boracic acid substituted.

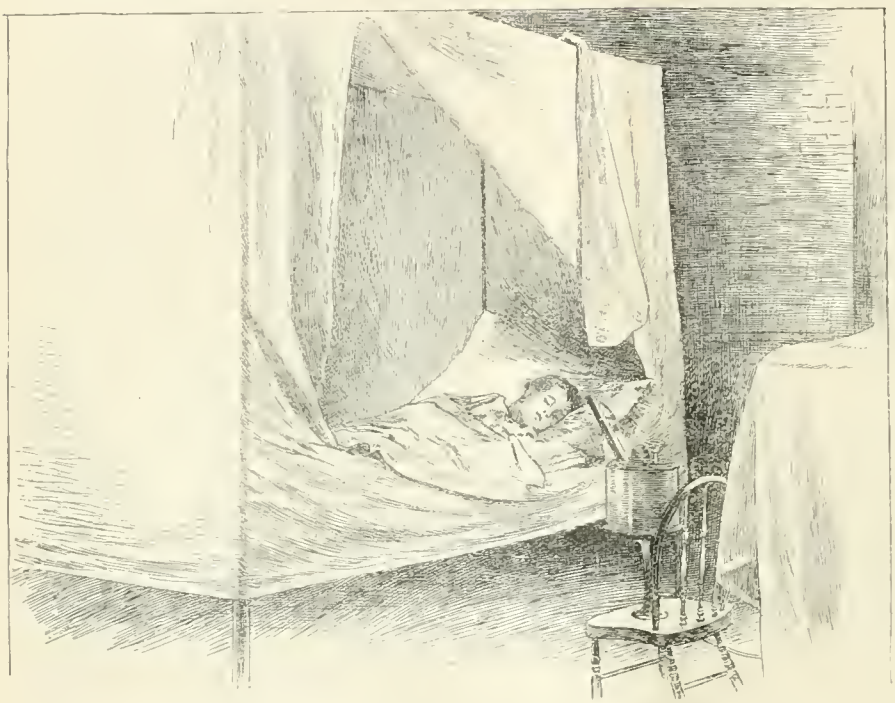
Now as to the frequency with which irrigation should be done. This varies with the severity of the case. When the nose and throat fill up rapidly with the secretions the irrigation should be at shorter intervals until the improvement in the amount of discharges renders less frequent irrigation equally effective. We must not forget, however, that irrigations, even if properly performed, are accompanied by more or less disturbance, and sometimes even violent resistance on the part of the patient, and that the strength of the patient is thus apt to become exhausted. It is of the utmost importance, therefore, if we would husband the vital energies of the patient and avoid heart failure, which is one of the chief dangers of diphtheria, that these irrigations be performed at intervals sufficiently far apart not to weaken the patient and yet sufficiently often to keep the nose and pharynx properly cleaned. Rarely do I think it necessary to subject the patients to irrigation more frequently than once in two hours, generally only once in three hours; both nose and throat being irrigated. As to how these irrigations should be done. The method that disturbs the patient the least should be the one selected; that I believe consists in the use of the fountain syringe. The patient, if a child, should be wrapped in a sheet, so as to pinion the arms, and then placed recumbent on the side upon a table or bed, a rubber sheet passing from the patient to a receptacle on the floor; the syringe is hung several feet above the level of the patient, and the nozzle, with a single opening, passed gently into the upper nostril as the patient lies on the side, parallel to the floor of the nasal cavity. The solution will wash out the nasal cavity and naso-pharynx, pass out through the lower nostril and through the mouth; the stream should be controlled so as to irritate the patient as little as possible. The lower nostril is then irrigated; then the patient remaining in the same position, and a large nozzle having been substituted, generally the larger rectal tube that goes with the syringe, the throat and mouth are irrigated, care being taken that the nozzle of the syringe is inserted well over the dorsum of the tongue, so that the solution may reach the pharynx.

The advantages of this form of douching are, 1st, the patient is recumbent, and thus the strength is not wasted; 2d, sufficiently large quantities of solution can be used without such interruption as it necessitated by the piston syringe; 3d, far less violence is necessary than in the use of the piston syringe; 4th, this irrigation can be accomplished with the least assistance, one nurse being generally sufficient to manage the tube and patient; 5th, there is the minimum of chance of washing bacilli into the larynx in cases in which the larynx is not previously affected. Occasionally where the plugs in the nose and posterior nares are so thick and firmly adherent that this douching does not dislodge them, the force of a piston syringe, with a soft rubber tip, so as not to injure the mucous membrane of the nose, may be employed; finally, and this is rarely necessary, a long probe, carefully guarded with cotton, may be passed through the nostrils, to be immediately followed by irrigation, which generally clears out the nostrils and keeps them open for the future. Swabbing, pencilling, and scraping the throat and nose are not useless, but are actually excessively injurious, owing to the abrasions which result upon the mucous membranes, each of these abrasions becoming immediately infected and diphtheritic.

I have occasionally blown small quantities of iodoform into the pharynx in cases where the appearance of the throat was extremely septic in character. I have never observed in such cases any symptom of iodoform-poisoning. Peroxide of hydrogen I have used in weak and strong solution, often the commercial solution of sixteen to seventeen per cent. by volume, pure; I have employed it as a spray and injected it with a glass syringe both in the throat and nose, and while theoretically the germicidal action of the peroxide of hydrogen should render it extremely useful in this disease, I have not found that the cases in which I have used it have done satisfactorily; the reason is that the preparation is extremely irritant, causing inflammation in the mucous membrane, with which it comes in contact when in strong solution, and this inflamed mucous membrane is apt to become diphtheritic. The weaker solutions, although non-irritant, are not strong enough to be germicidal nor bland enough for the mechanical washing effect. I must not neglect here to mention a local treatment for diphtheria recently proposed by Loeffler, and for which he makes enthusiastic claims. In the *Deutsche Medicinische Wochenschrift*, of October 18, 1894, Loeffler reports 71 patients treated in private practice by this new method, with 71 recoveries, all these cases having begun treatment early in the disease. Of 30 patients seen in hospital practice 5 died. All of these were seen in the second stage of the disease. The treatment is entirely local, and has for its object the destruction of the bacilli before their toxic products have been absorbed into the circulation. He applies to the diphtheritic mucous membrane of the pharynx or nose, as the case may be, the following solution: Alcohol, 60 volumes; toluol, 36 volumes; liq. ferri sesquichlorati, 4 volumes.

To alleviate the pain which the application of such a solution to the throat entails he adds 20 volumes of menthol. He finds that this solution, when brought in contact with thick culture layers of bacilli, in the laboratory, kills them in five seconds. The method of application consists in cleaning the affected mucous membrane with pledgets of cotton, then applying similar pledgets, thoroughly saturated with the solution, against the affected areas for the space of ten seconds. This should be repeated about every three hours at first, until the pulse becomes slower and the temperature falls; then only three times daily until membrane and bacilli disappear. The high authority of Loeffler's name would sanction the faithful trial of this remedy, but it is evidently open to the objection that it is scarcely applicable to cases of true diphtheritic croup, since here we cannot make these applications with any degree of completeness, especially where the process extends into the trachea. We come next to consider the local treatment of laryngeal true diphtheria, or membranous croup; here, as already hinted, the conditions are such as almost to preclude the use of fluid local remedies, for the reason that the mucous membrane of the larynx is not readily approachable; 2d, because fluid applications are apt to pass down through the trachea into the bronchi, and thus give rise to a pneumonia. Again, we have other conditions to treat in laryngeal diphtheria than in diphtheria of the pharynx and nose. For here the most prominent and disastrous effect of the disease is the dyspnœa resulting from, and varying with, the more or less perfect occlusion of the glottis and the lumen of the larynx and trachea; furthermore, the inhalation of the septic diphtheritic products located in the respiratory tract is apt to give rise to diphtheritic or septic bronchitis and pneumonia. The local treatment then, here has for its object, 1st, the prevention and removal of the swelling and false membrane affecting the mucous lining of the glottis, larynx, and trachea, and narrowing and occluding the calibre of the respiratory tract; 2d, the destruction of the bacilli and their toxic products in order to prevent the extension of the diphtheritic process into the bronchi and air-cells. It is evident that the form in which remedial applications can be best applied to this region is in the form of vapor or gas. Every inspiratory effort should,

if possible, result in the inhalation over the diseased mucous membrane of a curative vapor. There are many of these designed to produce various effects. Thus it has been thought that inhalation of steam reduces the swelling of the mucous membrane of the respiratory tract, to which much of the narrowing and mechanical occlusion of the tract is due; furthermore, these inhalations are supposed to hasten the separation and expulsion of the false membrane located in the larynx and trachea. It has always been a question in my mind whether the inhalation of the vapor of water has any such effect, for in cases in which there is false membrane and swelling in the pharynx, which we can observe, I have not noted any such effect from the inhalation of steam alone; but there is no doubt that such steam inhalations are extremely agreeable to the little sufferer, especially if they are warm and long continued. Steam inhalations in the treatment of croup was first recommended by Dr. L. H. Sayre, of this city, about thirty years ago. I must lay some stress upon the importance of having the steam warm; which is never the case in the ordinary steam spray apparatus known as the steam atomizer. In the Willard Parker Hospital there is in use an ordinary kettle, made of tin, with copper bottom, placed upon a tripod, with a Bunsen burner under it; this kettle has a long nozzle which delivers the steam about on a level with the child lying in a cot. A similar kettle, though not quite so large, can be bought at the stores and used in private practice. While ordinary steam gives the emollient effect of a poultice to the inflamed mucous membrane, it has been sought to use the steam as a vehicle for the application of germicidal agents to the bacteria located at the site of the disease in the larynx. I have thus used the oil of turpentine, creosote, and carbolic acid. With all of these agents I think some effect upon the dyspnœa is obtained. I have been led to believe that the effect of vapor of water thus medicated is better than that of vapor of water alone. The same apparatus is used as for ordinary steam, a small quantity of the turpentine or creosote or carbolic acid being poured upon the surface of the boiling water. These agents stimulate the patient to cough, and much of their beneficial effect should be ascribed to this circumstance; as to any germicidal action, the use of vapor of water, to which carbolic acid or creosote has been added in sufficient strength to produce such an effect, is irritating to the lungs and apt to give rise to pneumonia and bronchitis. I have yet to mention, however, one of the most important local applications of a vaporized remedy in croup, and that is the inhalation of the fumes of burning calomel. That mercury, when given internally in diphtheria, and particularly diphtheritic croup, is of the greatest value, an experience extending over seven or eight years has convinced me; and it appears to me that the beneficial effects of the inhalation of calomel fumes in cases of diphtheritic croup depends to a great extent upon the constitutional action of the mercurial vapor absorbed by the mouth, throat, and lungs. Nothnagel in his work on therapeutics shows that the action of inunctions of mercury cannot depend upon absorption through the skin; it depends upon the fact that such inunction, owing to the heat of the body, vaporizes the mercury; this mercurial vapor is directed by the clothing to the mouth, and thus inhaled and absorbed; how much more likely is it that sublimed calomel is absorbed by the vast absorbing surface represented by the air-cells and mucous membrane of the bronchi and trachea. I believe, then, that the only way in which calomel causes a diminution in the swelling of the affected portions of the respiratory tract, and hastens the loosening and liquefaction of the false membrane, is by being absorbed when thus locally applied, and producing the constitutional effects of the mercury. It is possible that it has some effect as a germicide locally, and the strongly irritant quality of the vapor certainly causes cough; but these results are only secondary, and certainly are inadequate to explain the excellent effect of the calomel fumigation in diminishing dyspnœa and softening the cough of cases of membranous croup. The calomel should be burned under a tent formed over the bed of the patient. The tent should be as complete as possible, and not too large, so as not to require too much calomel for fumigation. The calomel should be sublimed upon a tin plate over an alcohol lamp. I present herewith a calomel sublimer, which I consider excellent, used at the Willard Parker Hospital. The quantity that should be burned is about ten grains every two or three hours, depending upon the severity of the dyspnœa, until the patient is relieved; here, as from the internal administration of mercury, constitutional effects, such as diarrhœa, salivation, etc., should be looked out for, and the procedure guided accordingly. Salivation, however, is very rare in young children. I have neglected to state that the tent over the cot of these little croup patients is an important factor in the local treatment of croup, for even steam inhalations can only be done effectively if the patient is made to breathe the air of a confined space filled with steam. There are, of course, a vast number of other local remedial medicinal agents for diphtheritic laryngitis, but those I have mentioned are the ones with which I have had the most experience.



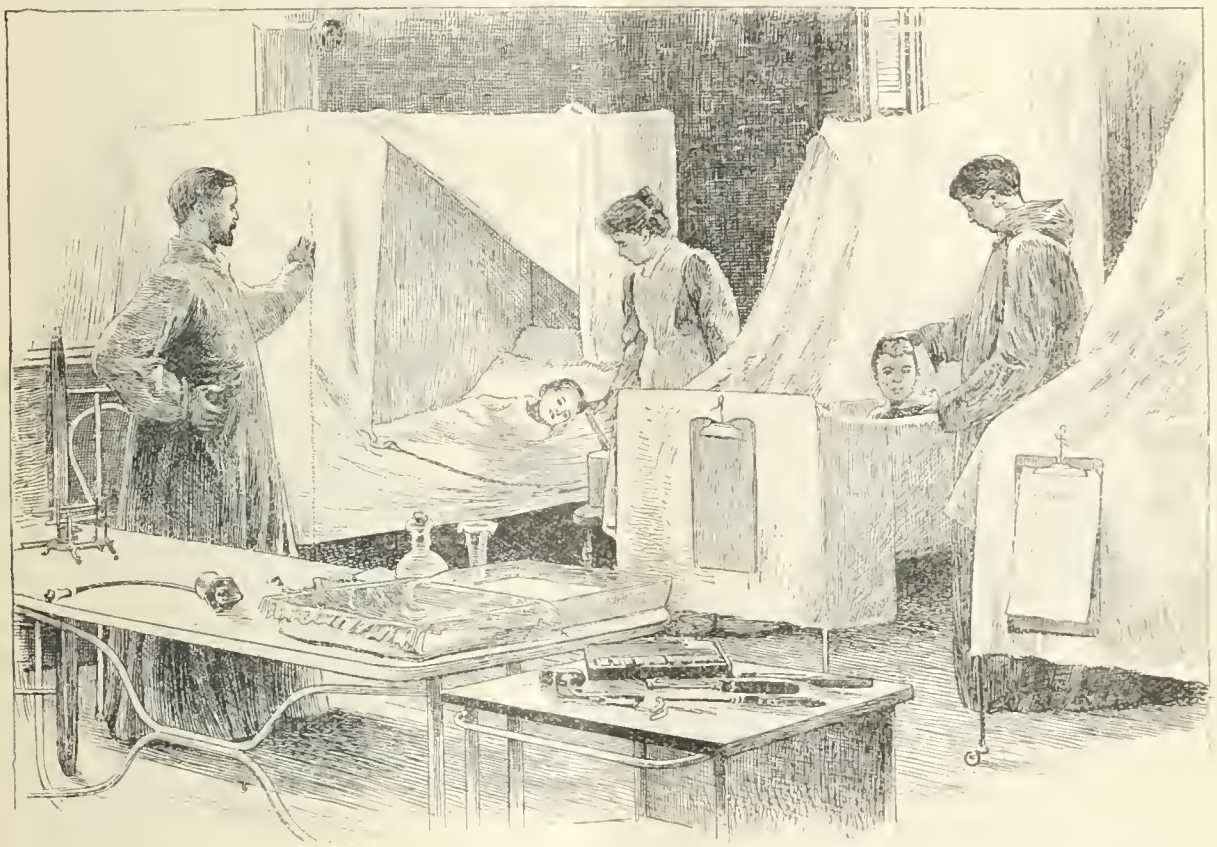
Showing Position of Calomel Fumigation.

Finally, we have for the relief of the dyspnœa in diphtheritic laryngitis which threatens to become fatal two surgical procedures, the one ancient—tracheotomy; the second recent, modern, and American—the method that the world owes to the genius of O'Dwyer, intubation. It is customary in these days to contrast these two methods of operating, with the view of finding

which should be preferred. A comparison of the two procedures is as preposterous as it would be to discuss whether it is better to extract a foreign body from the œsophagus, or perform œsophagotomy or gastrotomy. In cases in which the milder operation is sufficient, certainly the severer and more fatal operation should never be performed. The object of the operative procedure being to relieve dyspnœa, that operation should be selected which can do it most effectively and most safely—by safely we mean ultimate as well as immediate safety. It will be conceded without argument that even in the hands of the most skilful surgeon tracheotomy is by far a more serious operation than intubation; but to enumerate all of the advantages of the latter operation is hardly necessary when it is remembered that the percentages of recovery from intubation, taking all the cases, are vastly better than those from tracheotomy. Many parents who will subject their child suffering from croup to intubation would refuse tracheotomy; superior surgical skill is not requisite to its performance. There is little or no danger from the operation, if we exclude the possibility of pushing down false membrane in front of the tube, which occurs rather rarely. The after-treatment is simple, and does not absolutely require trained nurses for its proper fulfilment. There is no wound to heal after the tube is removed. The objection to intubation is the difficulty in feeding patients with a tube in the larynx; even small quantities of liquids when swallowed pass into the trachea instead of the œsophagus, and gives rise to a pneumonia, due to the lodgement of liquids in the smaller bronchi and air-vesicles. And yet taking all the advantages and disadvantages into consideration, I think we may formulate the rule that in cases in which the dyspnœa can be relieved by intubation, this operation should be performed. If subsequently the tube no longer relieves the dyspnœa, then a larger tube may be tried, or tracheotomy may be performed. I should then limit the performance of tracheotomy to those cases of membranous croup in which the tube does not relieve the dyspnœa primarily, or secondarily, when the disease having extended below the level of the tube, the latter no longer is effective.

It is hardly within the province of this paper to discuss the method of the performance of these two operations. A few important points in management of intubation cases cannot be too often repeated. 1. I have found the best tubes those most recently manufactured, with the bulbous ends. 2. In inserting the tube the gag should be placed well back between the last molar teeth. 3. The tube should be thoroughly sterilized before being inserted by dipping in boiling water. I think that frequently the extension of the disease below the level of the tube is due to the use of a dirty tube. 4. Liquids should be fed the patients in small quantities, the patient lying on the back, on the lap of the nurse, with the head thrown back, thus bringing the back of the pharynx on a lower level than the larynx. 5. If the baby be a nursing baby it should be fed in that way even when intubated. I have been accustomed, in older children, where in spite of all efforts neither food nor drink can be swallowed, to remove the tube every second day, sometimes even every day after the second day, feed the patient, and then replace the tube; this, however, is very rarely necessary. I generally order ice for the thirst instead of water; ice-cream, condensed milk mixed with ordinary milk in equal parts, thick broth, the yolk of eggs, these are the chief articles of diet while the tube is *in situ*. Before extracting the tube the blades of the extractor should be examined to see that they are firm. I have seen one of them break off just as the extractor had been placed in the mouth. The patient should be kept under a tent filled with warm steam while the tube is in the larynx.

A word as to emetics. I do not ever think it necessary to administer emetics, except at the beginning of the disease, and then chiefly as a means of differential diagnosis between true and false croup. The latter cases are cured by a sharp emetic, and little other treatment, while true croup is temporarily relieved, but soon the membrane reforms, the swelling returns, and



View of Croup Tents.

the patient is as bad as ever. To relieve dyspnœa in true diphtheritic laryngitis, emesis can be but a temporary expedient. The emetic I prefer in all of these cases is the yellow subsulphate of mercury.

Constitutional Treatment.—I do not think that anyone will question that by far the most frequent cause of death from diphtheria, except when it is located in the larynx, is the pathogenic action of the toxin formed under the influence of the Loeffler bacillus. This toxin is absorbed into the general circulation, and gives rise to the familiar manifestations of toxic diphtheria, such as fever, swelling of the lymphatics, disturbance of the heart's action, manifested by rapid and feeble pulse, and sometimes heart failure, inflammation of the kidneys, lungs, brain and its meninges, the formation of abscesses in different portions of the body, and in the later stages of the disease, paralysis due to toxæmia and inflammations of the peripheral and central nervous system. All of these are chiefly the result, in a general way, of the absorption of the toxic material into the blood. Even where the inflammatory lesions are due to the direct extension of the diphtheritic process, as in diphtheritic bronchitis, and pneumonia, inflammation of the middle ear and mastoid sinus, the absorption of toxins into the blood adds greatly to the danger. The constitutional treatment of diphtheria, then, is by far the most important of any that we have considered. Such constitutional remedies at present in use in this disease are either symptomatic, empirical, or rational. The symptomatic remedies are those whose use is intended to counteract the evil symptoms of the action of the toxin. Thus digitalis, strychnine, caffeine, etc., are intended to obviate and remove the signs of weak heart's action; empirical remedies are such as have been found to exert a favorable influence upon the constitutional manifestations of diphtheria, by experience, without a really adequate explanation of their action being known. In this group I would class the most important remedies that we have against the action of the diphtheritic toxin, bichloride of mercury and tincture of the chloride of iron, although some might class both of these among the so-called rational remedies for diphtheria. Finally, we have the most recent remedy for diphtheria toxin, the so-called antitoxin treatment, which, if all that has been claimed for it turns out to be true, will, as is always the case with rational remedies, replace the empirical absolutely.

The Method of Intubating.

In considering the symptomatic remedies for the constitutional symptoms produced by diphtheria toxin, one of the most important symptoms which comes up for treatment is the fever. This varies in amount, but not in proportion to the gravity of the disease. Very septic cases of diphtheria may have little or no fever, while mild cases sometimes "run" high temperatures. At the beginning of the disease the fever is probably due to the local inflammation of the tonsils and not to the absorption of toxins. This fever will subside within the first twenty-four hours, so that a patient with a high temperature at the outset may be bright and smiling on the following morning, while the throat is found to be full of membrane. The treatment of the fever of diphtheria should never be by antipyretics. These drugs weaken the activity of the heart. Hydrotherapy only should be used. This includes cold compresses about the neck for their local action, sponging with a mixture of five parts cold water and one part alcohol, and Ziemssen's baths. The temperature does not require any treatment if it be below 102° F., and cold sponging in a warm room, followed by gentle rubbing with a dry towel is to be preferred to baths. The frequency of the sponging or baths will depend upon the temperature, and should be suspended entirely when the temperature has fallen to 101° F. In this connection it is well to remember that a small amount of fever has a sustaining rather than a weakening effect upon the pulse. The sustaining of the weak heart of diphtheria is the most important symptomatic indication in the treatment of this disease. It should be enforced in every case before the appearance of the signs of a failing heart. In diphtheria as little work should be placed upon the heart as possible. Such patients should not sit up, but maintain a recumbent position. The patient should be kept lying in bed, as long as membrane is present, however slight the symptoms may be. Severe cases should be kept in bed for weeks after the membrane has disappeared. All local applications made to the throat should be so made with the least possible physical disturbances, and, when possible, with the patient in the recumbent position. In an excessively excitable patient I frequently prefer to suspend for a time the local treatment of the disease rather than exhaust the patient. Indeed, the frequency of local applications, such as irrigation, should depend partly upon the severity of the local disease, and partly upon the strength and resistance of the patient to the local treatment. Stimulants and diet should be such as will best maintain the strength of the heart. Thus I give whiskey, brandy, and other alcoholics, together with a fluid diet, milk, beef-broth and beef-juice, eggs, etc., avoiding all forms of diet and stimulation which cause vomiting. In severely sick children, where the

patient refuses food and stimulants, rectal feeding must be employed; I have no experience in feeding such patients with the stomach-tube; the objection to this is the struggling of the patient when the tube is passed, although some cases, I have no doubt, will do better fed in this way than by the rectum. As much of the alcoholic and fluid diet as possible should be given at frequent intervals and in small quantities at a time. Of the alcoholic stimulants, whiskey is to be preferred, diluted with milk or water.

Of stimulant drugs strychnine should be given at the very beginning, in order that its maximum physiological effect may be attained about the time when the heart begins to flag. It is best to give considerable doses, frequently repeated; to a child two years of age $\frac{1}{120}$ of a grain every two or three hours if necessary. Should symptoms of heart-failure occur, hypodermatic injections of strychnine, nitro-glycerine, and caffeine, in the shape of the double salicylate of soda and caffeine, are indicated. Counter-irritation to the heart is also indicated. Digitalis does not act well, in my experience, in the heart-failure of diphtheria.

There has always been in this disease the desire, on the part of our profession, to discover a specific remedy that is common to all frequently fatal diseases; such specific remedies have generally been advocated upon an empirical basis. The empirical drugs in treating diphtheria, with which I have had experience, are the tincture of the chloride of iron, and the bichloride of mercury. I do not think that the use of either of these is really empirical in the treatment of diphtheria. The tincture of the chloride of iron in large doses, fifteen to sixty drops every hour or two, undiluted and only mixed with a little glycerine, certainly has some local effect upon the throat as it is swallowed. The recommendation by Loeffler of the perchloride of iron solution as a local specific against diphtheria, of which I have already spoken, would indicate its local value; when swallowed, if absorbed by the stomach, it would appear to act as a blood stimulant, supporting the heart through a wasting disease. This remedy in large doses, and only in such doses has it any possible effect, is very popular, having the sanction of the highest authority. I must protest against the administration of this drug in small doses, at long intervals, unless the physician intends it to act simply as a placebo.

While I consider the iron treatment as given above adequate in milder cases of diphtheria, I do not rely upon it exclusively in severer cases, but have much more confidence in the use of large and frequently repeated doses of corrosive sublimate. This treatment of diphtheria and diphtheritic croup was first introduced into this city by Dr. A. Jacobi, and unless the antitoxin treatment should prove all that is claimed for it abroad, I have considered it by far the most valuable remedial agent given to us in diphtheria. Its good effects are as remarkable in the treatment of diphtheritic croup as in the treatment of general diphtheria. In this respect it differs widely from the iron treatment; I consider the latter absolutely valueless in cases of uncomplicated membranous croup, with no septic manifestations, while the mercurial treatment is to the medical treatment of true croup what intubation is to the operative treatment of the same disease. Fully half the cases of membranous croup, if properly treated sufficiently early by corrosive sublimate, will not require intubation of the larynx, and those that have been intubated do far better if they have been under the influence of the mercurial sublimate solution before the intubation, even if this has not succeeded in relieving them without the operation. I have already stated that the most valuable local remedial agent in croup is calomel fumigation, and I am convinced that this is of value only through the absorption of the mercury by the mucous membrane of the bronchi and through the air-vesicles. In other words, calomel fumigation only hastens the saturation of the blood with mercury. As to why the internal administration of the bichloride of mercury is of such value in diphtheria I cannot say. Mercury certainly is excreted by the mucous membrane of the respiratory tract. It increases the secretion of the mucous follicles as it does that of saliva, and probably in this way accelerates the loosening and separation of the false membrane. Upon pharyngeal diphtheria it can possibly exert a slight local effect, of an antiseptic character, as the hourly or half-hourly dose is swallowed. As to whether it exerts a destructive action upon the diphtheria toxins in the blood is very doubtful. Nevertheless clinically this is by far the most powerful curative medicinal agent in the treatment of diphtheria. It should be given in comparatively large doses frequently repeated. I give to a baby a year old $\frac{1}{60}$ grain every half-hour or hour, and this can be continued for several days if necessary. Salivation in these little patients is very rare. The occurrence of mercurial diarrhœa is the chief indication for the suspension of the remedy. It is rarely or never vomited. It should be given alone, dissolved in distilled water; never given in a mixture with iron, never mixed with an organic drug or sirup. If albumin be present in the urine when the treatment is begun, its increase should signify a diminution of the drug; if no albumin is present in the urine, its appearance means a suspension or diminution of the remedy. The iron treatment is also contra-indicated if the albumin in the urine of the patient is increasing.

We now come to the consideration of the most remarkable method of treatment that has ever been proposed for true diphtheria, and the only one to which the term rational can be applied, namely, the *serum therapy* as applied to this disease, that is to say, the antitoxin treatment of diphtheria.

By the methods hitherto advocated, diphtheria has been treated with considerable success; indeed, with rather more success than they have had in Germany or France, judging from statistics recently published. And yet diphtheria has been a frightful scourge to very young children, killing larger numbers of them than perhaps any other acute infectious disease. With the view of eradicating this scourge bacteriologists and clinicians turned their attention to discovering some method by which human beings could be rendered immune to attacks of true diphtheria, and in a general way to attacks of other acute infectious diseases. While methods were discovered by which animals, sensitive to diphtheria, could be rendered immune to the action of the Loeffler bacillus and its toxin, it was found that similar principles could be applied, in the treatment of diphtheria which had already developed in animals, with success. As early as 1868 an Italian had vaccinated patients suffering from diphtheria with diphtheritic virus, and under this method of treatment lost but one case out of fifteen treated. Bagola, of Sienna, using a like method of treatment, had similar results in twenty-nine cases. One can readily see the objections, however, to a method of treatment, or of procuring immunity which would necessitate the inoculation of human beings with active poison like diphtheria virus, or the injection of cultures of diphtheria bacilli into the blood of human beings with the object of rendering such persons immune; the reaction to the poison might be sufficiently great to cause a fatal diphtheria. Brieger and Fraenkel succeeded in rendering guinea-pigs immune against virulent cultures of the diphtheria bacillus by injecting bouillon cultures, three weeks old, of Loeffler bacilli; they sterilized these cultures by exposure for an hour to a temperature of 60 to 70° C. They injected from 10 to 20 c.c. subcutaneously. At the end of two weeks immunity was complete. It was found that all animals that are susceptible to diphtheria can be rendered immune to the disease by injecting into their bodies pure cultures of Loeffler in bouillon

of gradually increasing virulence, beginning with the weakest cultures, such as will produce only the slightest reaction, and terminating when the most virulent cultures can be injected without producing any reaction either locally or generally. Such animals retain their immunity against diphtheria for a considerable period of time, varying in different animals, but not in any case permanently.

Behring should have the credit of first having discovered the fact that the blood-serum of animals that have been thus rendered immune to diphtheria contains some substance which neutralizes the toxic agent contained in virulent cultures of Loeffler bacilli; the blood-

Proper Method of Feeding Intubated Patient.

serum of such animals produced this wonderful effect when it was added to the filtered virulent cultures outside of the body, as well as when the cultures were injected into the living animal together with, immediately preceded or followed by, an injection of the blood-serum of the immune animal. Indeed he found that when the toxin is injected into a susceptible animal several hours before the injection of the blood-serum of an immunized animal, the diphtheria toxin is still neutralized and the animal recovers. This protection and curative influence of the serum of animals rendered immune to diphtheria was observed not only against the toxin but against injections of the pure cultures of the bacillus. Upon the application of these discoveries to the human body depends the serum therapy of diphtheria in human beings, and from what we have said it will be seen that the following points are of importance in this connection: 1. How is the toxin, which is required for rendering animals immune, made and used? 2. How are animals rendered immune? 3. How is the blood-serum of immune animals containing the antitoxin to produce its effects? 4. How is it to be applied, as to dose, frequency of application, etc., in the therapy and prevention of diphtheria? 5. What are the therapeutic benefits of the antitoxin treatment as compared with other forms of treatment of diphtheria?

1. The toxin for immunizing animals to diphtheria poison, that is, inducing in them, as it were, the diphtheria habit, is best made by cultivating extemely virulent bacilli in a current of moist air.[1] Alkaline bouillor containing two per cent. of peptone is placed in flat-bottomed vessels, supplied with a lateral tube for the admission of air above the level of the fluid. These solutions are sterilized and inoculated with very poisonous Loeffler bacilli, and heated in an oven to 37° C. When the culture has begun, a stream of air is admitted. After three or four weeks the culture is rich in toxins, and can be used for purposes of immunization of animals. These cultures are filtered through a porcelain filter. The clear fluid remaining is kept in the dark, in bottles well corked, at ordinary temperatures. 0.10 c.c. of this toxin, thus kept, will kill a guinea-pig weighing 300 gm. in forty-eight to sixty hours.

2. How are animals rendered immune? The toxin above described is too strong for a first injection; it produces a fatal diphtheria. It must therefore be diluted. Roux and Vaillard have used for this purpose iodine. Before injecting they dilute the toxin with one-quarter of its volume of Gram's solution, and after a few seconds inject it under the skin. The amount injected depends upon the size of the animal. An ordinary rabbit will stand a first injection of 0.5 c.c. of this solution of toxin and iodine. After a few days, the slight reaction having subsided, another injection is given in larger doses, and thus for a few weeks, the dose being gradually increased and the dilution with iodine diminished until the pure toxine is employed. The injection should be suspended whenever the animal shows a diminution in weight, for otherwise it may die. Some animals are more susceptible than others. Dogs thus immunized give a good serum. Sheep, goats, and cows are very apt to die during the process, and great care is required in these animals to succeed in reaching the stage of immunity. For many reasons the horse has proved to be the best animal for the purpose. The horse has the advantage of not being very susceptible to the poison; 2.5 c.c. of the strong toxin often causing very little fever and very slight local œdema. When immunized the horse furnishes a large amount of serum containing antitoxin, and the serum when injected under the human skin gives rise to no irritation and is entirely harmless. This animal is accordingly preferred by German and French experimenters for making antitoxin for therapeutic and prophylactic purposes. Vaillard reports as to the length of time necessary to immunize a horse to diphtheria. Beginning with an injection of $\frac{1}{4}$ c.c. of the iodine toxin mixture he was able within two months and twenty days to inject 250 c.c. of the pure toxin without producing any local reaction or increase of temperature.

3. How does the blood-serum of immune animals containing antitoxin produce its effects? Aronson[2] says that his experiments prove the antitoxin contained in the blood-serum of immune animals directly destroys the toxin of diphtheria. This action occurs in the laboratory as well as in the living organism. Buchner and others, on the other hand, believe that there is no destructive action between the poison and the antitoxin.

If an animal receives a proper dose of serum, it resists a subsequent injection of toxin which would kill a guinea-pig of like weight not previously treated with the serum. The same result will follow if the toxin and antitoxin be injected together, or if the toxin be injected first, followed by the antitoxin at an interval of a few hours. In all these the guinea-pig will remain healthy, provided the proper proportion of the toxin and antitoxin be maintained. The quantity of serum necessary for a cure varies with the weight of the animal, the amount of toxin to be neutralized, and the time elapsed between the injection of the curative serum and the toxin. We know very little of the real

[1] Roux and Martine: Annales de l'Inst. Pasteur, November, 1894.
[2] Berliner klinische Wochenschrift, 1895, No. 15, p. 356.

nature of the "antitoxin" constituent of the antidiphtheritic serum.

4. As to the dose and method of application of the serum containing the antitoxin. The dose varies with the strength of the serum. Ehrlich has proposed a method for estimating this strength for any given sample of antitoxin serum. The unit of strength is $\frac{1}{10}$ of c.c. of such a serum, which so neutralizes $\frac{3}{10}$ c.c. of normal toxin that the mixture injected under the skin of a guinea-pig produces no local manifestation. The blood-serum used for therapy in human diphtheria is obtained by drawing the blood from the jugular vein. From this a perfectly clear serum is separated. To it is added a small amount of trikresol to keep it from decomposition. The immunizing power of the serum obtained from these animals is so great as to reach 100,000; that is to say, the serum will neutralize a dose of toxin that would kill the experimental animal, when it, the serum, is administered in the weight of 1 to 100,000 of the weight of the animal.

Aronson[1] has succeeded recently in manufacturing very much more powerful antitoxin serum by using for his animals toxin obtained from very old and extraordinarily virulent diphtheria cultures. Behring's normal antitoxin, Roux normal antitoxin, and Aronson's immunization solution are about of equal strength. Aronson's stronger solution is three times stronger than the immunization solution. From experiments with the serum on animals we know that the dose of antitoxin serum for therapeutic purposes necessarily varies with the weight of the individual, the virulence of the diphtheritic manifestations, and the length of time that has elapsed since the patient has been affected with the first symptoms of the disease. Behring's, Roux's, and Aronson's immunization, or weaker solution, all have the effectiveness of 50,000 to 100,000. The dose is, for theraaeutic purposes, 20 c.c. as a first injection, under the skin between the shoulder-blades or in the flank. If a bacteriological examination shows the presence of Loeffler bacilli, Roux gives 10 c.c. more in twenty-four hours. If no Loeffler are shown the case receives no more antitoxin. These two injections, made under antiseptic precautions, generally suffice, although in some cases with high temperature and rapid and feeble pulse a third injection may be given. No evil results follow, either locally or generally, according to every observer who has reported his cases. Some observers have found a red rash following the injection of the antitoxin. In the cases treated at the Willard Parker Hospital, but two cases out of twenty showed a rash, of doubtful character, following the eruption. The antitoxin was used for purposes of rendering human subjects immune to diphtheria by Aronson, Roux, and others, but I have never seen it used for this purpose. It must not be forgotten that any immunity to diphtheria is only a temporary matter, for this is not a disease in which one, or at most two attacks, grant immunity. Some patients have true diphtheria several times a year.

At the Willard Parker Hospital twenty cases, recently reported to a section of this Academy by the resident physician, were treated during the time of my service. The preparation used was Aronson's stronger antitoxin solution. The dose varied from 5 to 12 c.c.; the total number of injections given to all the twenty patients was thirty—an average of one and a half injections per patient—much less than Roux or the German authorities give.

5. We come finally to consider what benefits have been derived from the antitoxin treatment of diphtheria, and how do they compare with results obtained by other methods of treatment. In the year 1892 there were 4,654 cases of diphtheria reported to the Bureau of Contagious Diseases in the city of New York—1,436 died. In 1891 there were 4,874 cases reported, of which 1,361 died, a death-rate for the two years of 29⅓ per cent. During 1892, at the Willard Parker Hospital, there were treated for diphtheria 205 cases; died during the year, 79; death-rate, about 25.4 per cent.; but in children under five years of age the death-rate was 44.55 per cent., and from five to sixteen years, 11.7 per cent. only. The number of cases reported by physicians to the Health Department is necessarily far less than the number really occurring, for the mild cases are frequently not reported, so that the diphtheria death-rate for the city is probably much lower than that given above. The death-rate above given was under the customary treatment of diphtheria.

Curiously enough, the death-rate from diphtheria in the cities in Europe is very much larger than in ours. Martin and Chaillon report that in the Hospital des Enfants Malades there were treated, from 1890 to 1894, 3,971 children, of which 51.71 per cent. died—more than twice the death-rate at the Willard Parker Hospital for 1892; and probably more than twice the death-rate in the city of New York at large for 1891–92.

Similar statistics are obtainable from Berlin and Vienna, hence we must conclude either that the diphtheria in these cities is far more virulent than ours, or that our present methods of treating diphtheria are twice as efficacious as those hitherto pursued on the other side of the Atlantic.

Under antitoxin injections of the cases treated at the Hospital des Enfants Malades from February 1 to July 24, 1894, of 448 children, 109 died, or 24⅓ per cent. At the same time, of 500 cases treated at the Hospital Trousseau, 316 died, or 63⅓ per cent.—a frightful death-rate for this disease. Deducting from the 448 cases 128 that were not true diphtheria, and 20 cases that were not treated, the death-rate is 78 out of 300 cases, or twenty-six per cent. The improved death-rate, then, from antitoxin treatment at Paris, is not as low as our own death-rate under old forms of treatment.

Aronson, on the other hand, reports a reduction of mortality in cases of true diphtheria treated by antitoxin to twelve to thirteen per cent., against thirty-two to thirty-seven per cent., under the old methods of treatment. Katz reports 163 cases of true diphtheria, with a death-rate of thirteen to fourteen per cent., treated by antitoxin. All observers agree that of cases coming under treatment during the first day of the disease all recover, and the further the disease has advanced before the beginning of the treatment the less hope there is from the antitoxin treatment. Of the 20 cases treated at the Willard Parker Hospital there were admitted, and treatment began

Day of the Disease	Number of Cases.		Died.	Per cent.
Third	7	of which	2	28½
Fourth	4	" "	0	0
Fifth	5	" "	1	20
Sixth	1	" "	0	0
Seventh	2	" "	1	50
Eighth	1	" "	1	100

In all 5 died, being twenty per cent. of the cases.

In view of the fact that the most reliable observers on the other side of the Atlantic report such a vast improvement in the death-rate from true diphtheria, it is proper for us to look to the serum therapy as applied to this disease with a great deal of hope of benefit from its use in this country, but in view of the discrepancy between the results obtained by present methods of treatment in this country, as compared with results from the same treatment abroad, we must suspend judgment as to the value of antitoxin treatment in this country until we shall have proved by the treatment of thousands of cases as great a reduction in our present death-rate, relatively, as they have succeeded in obtaining in Europe. I have purposely not mentioned the complications of diphtheria in this paper, inasmuch as the subject is obviously too vast for consideration in one paper; it has been rather the aim to give a general outline of the treatment of diphtheria as followed in hospital and private practice.

MANIPULATION IN THE TREATMENT OF ASTHMA.

By ORRICK METCALFE, M.D.,

NEW YORK.

In an article published in the MEDICAL RECORD, April 7, 1894, I spoke of the treatment of cough by manipulation. I find that I did not describe the process with that clearness which is necessary to the full understanding of a new method. I use the word manipulation because it seems to me that it expresses rather better what is done than the terms rubbing and massage. There is some rubbing done, but sometimes pressure alone, for a longer or shorter time, is all that is necessary to afford relief. The rubbing is never done superficially, confining the influence of the force expended to the skin. As I practise manipulation there is pressure, combined with a very limited degree of rotary motion. The degree of pressure depends upon the sensitiveness of the part operated on and the nearness to the surface. Where the tissues involved are deep-seated the pressure is necessarily firmer. As to how manipulation brings the relief I have no theory, but when a muscle is thereby freed from pain, I think I know why it is able to perform its function better, no matter what that function is. The length of time for which the manipulation is to be kept up depends upon circumstances—upon what is attempted and how readily the trouble yields. Sometimes ten minutes will suffice, sometimes half an hour may be profitably spent. Generally speaking, after a few minutes spent in manipulation, the patient is requested to cough, and his success in expelling the mucus determines the conduct of the doctor as to the repetition of the treatment. After the first treatment there is almost invariably increased soreness of the part where the manipulation was done. After the second treatment, say at the end of twenty-four hours, the soreness gradually and steadily diminishes, till it disappears altogether. Some persons to whom I have tried to explain my method entertain the idea that I expect to force the mucus from the bronchial tubes by external pressure. I have not the remotest idea of anything of the sort. I know that would be impossible, but my experience has taught me that the muscles engaged in respiration are correlated with the mucous membrane of the bronchial tubes in such a way that the manipulation of the muscles will cause a flow of mucus, sometimes very free, from the mucous membrane of the bronchial tubes. I have demonstrated this too often to have the slightest doubt in regard to it.

Notwithstanding I knew this was the case in pneumonia and bronchitis, I never thought of applying the same principle in the treatment of asthma until I was told by an asthmatic that his severest attack was brought on by laughing. At the time he was seized he was feeling very well, and was waiting, with a tool-box on his arm, for the hour of seven to strike, when a funny story told by a fellow-carpenter started him to laughing, and the laughing brought on such a severe attack of asthma that he had to be carried to his home in a hack. It occurred to me that the convulsive action of the muscles engaged in laughing was the cause of trouble, and that possibly an examination would reveal an unhealthy condition of those muscles. Closing with this conception I determined to try, on the next opportunity, the effect of manipulation on the muscles on the sides of the chest, and not on those of the back or the abdomen. It was not long before a case presented itself. It was a well-marked case of asthma without heart complication. There was resonance over the whole chest, with very feeble and inspiratory murmur, prolonged expiration with sibilant râle. There was what asthmatics call tight-breathing and inability to expectorate. As good fortune would have it, I was right in choosing the muscles on the side of the chest as the seat of trouble; for in a few minutes after I began to manipulate she began to expectorate, and kept it up so long and so profusely that I had finally to administer a dose of morphine to arrest it. In this case the effect of the manipulation was demonstrated, so far as causing a free flow of mucus was concerned, and affording such relief as enabled her to lie down, which she could not do before. I saw her two or three times after her visit to my office, and learned that she continued to be comfortable. Remember that my object in having this patient come to my office was not to cure her, nor treat her beyond the point of testing the conception as to the relation between the outer and the inner man, and the demonstration of that relation by manipulation.

The next case was that of a man, nearly seventy years of age, who had asthma for fifteen or twenty years. He was unable to lie down, and walked across the room with difficulty. My visit was to his son, ill with typhoid fever; but seeing the old man's distress I proposed to give him some relief, expecting to find the seat of trouble on the sides of the chest; but, to my great disappointment, manipulation made no impression. Holding fast to the conception that the muscles engaged in respiration were at fault, I sought further, guided by his answer to a question, until I stumbled on the spot, about four inches long, to right of sternum and four inches below the clavicle. This spot, on pressure, was very painful, though he complained of no pain before I touched it. In a few minutes there was very free expectoration, so free as to be distressing. After the coughing was over he breathed much better, and the following night he lay down and slept comfortably. I saw this patient occasionally as a study. He was made very much more comfortable by my treatment, and was able to walk a mile and back without distress.

The third case was that of a woman, about fifty years of age, who was suffering from an acute attack of asthma, which had prevented her from lying down for three weeks. In this case there was no heart trouble, but the signs of asthma were well marked, as described in the first. The manipulation of the sides of the thorax and the sternum soon started a free flow of mucus. In fifteen minutes she could lie down comfortably. As she had been unable to lie down at night, I went at 10.30 P.M. to see if the good effects of my work done at 2 P.M. were lasting, and found her lying down, not only flat but without a pillow. I saw her twice afterward, showed her husband how to treat her, and learned that she had no further trouble.

This work having been done in Mississippi, I was desirous of seeing if similar cases would be amenable to the same treatment in New York City. The principle on which the treatment is based is as applicable here as there, whether the case be one of common asthma or of that phase of the trouble connected with hay fever. Of this disease the cases of a man, aged fifty, who had asthma, with the signs before related, and that of a woman, aged thirty-five, who, from the history she gives must have had hay fever with lung complication for nearly fifteen years, may be mentioned. The man was seen on October 2d, when I found less soreness than usual, but great distress on walking and inability to lie down at night, when he has to sleep propped up on four pillows. In his case the muscles attached to the scapula were very firmly contracted, so much so that at the first visit it was impossible to insert my fingers under the lower angle of the bone. In spite of the rigidity of these muscles the manipulation did good. He breathed better when he left than when he came to me, and slept better the following night than he had done for some time. The same treatment was pursued on three subsequent days, there being a gradual improvement from day to day. After October 5th there was an unavoidable interruption in the treatment for nearly three weeks; but during that time there was no ground lost. After the third treatment he ran up the "L" stairs, which he had not

been able to do for ten years. The treatment was resumed and the patient has been seen fourteen times since October 26th. Since he has been coming to me he has walked several times from Forty-ninth Street, near East River, to Sixth Avenue and Twenty-eighth Street. This, he says, he has been unable to do for more than ten years. He ascends the stairs of his own house more comfortably than he has done for a long time, uses only two pillows in sleeping, and when he finds himself off his pillows is not distressed by it as formerly. Where it is possible to effect a cure in such cases, it is not impossible, except by slow degrees, to restore the healthy tone to muscles that have been chronically contracted, and to others that have been atrophied by disuse. It must, even when the right thing is done, take time for the mucous membrane to be restored to a healthy condition.

In the case of the woman with hay fever and asthma there has been a steady improvement under manipulation. She illustrates one feature of lung trouble which to me was misleading when I began to study the matter. The clearing of the throat, as it is called, I used to regard as an indication of trouble in the larynx or trachea, but now I know that it may indicate irritation anywhere in the lung. It is in this way that I arrive at the following conclusion: Whenever the seat of trouble is such that the râle can be detected, manipulation will enable the patient to expel the mucus, after which the râle is no longer heard and the disposition to clear the throat ceases. I have seen this demonstrated so often that when the asthmatic complains of distress about the trachea I know the trouble may not be there in many cases, but may have a cause more deeply seated. In this case the evidence of connection between the nose, where hay fever generally starts, and the lungs, is very marked. As the asthma improves those peculiarities of the hay-fever sufferer disappear. There is less sensitiveness to currents of air, and less general irritability. Another interesting feature of this form of asthma is the effect that the manipulation of certain muscles has on the expansion of a certain portion of the lung. This point I have studied so carefully and so often that I do not think I am mistaken about it.

Does the marked and prompt relief afforded in the cases referred to, and in others that could be mentioned, justify the hope that the treatment of asthma by manipulation may be in the right direction and may eventually lead to better results than have been hitherto reached?

The Medical Profession and the Indiana Congressman.—The *Journal of the American Medical Association* has this to say about Congressman Holman: "Every physician residing in the Fourth Indiana Congressional District should remember that W. S. Holman, as chairman of the Appropriations Committee of the House of Representatives, did all he could to defeat the appropriation for the Pan-American Medical Congress, and that he persistently votes against every measure which is for the advancement of medical science. If he were governed by purely patriotic motives no one could impugn them, but when we know that a worthless member of his family was foisted on the Geological Survey and there retained for a long time on the public pay-roll, we can assume reasonably that his so-called 'watch-dog-of-the-Treasury' act is one of hypocrisy, and for demagogic purposes only. If the doctors in the Fourth Indiana District will exert themselves a little, this interesting person will be properly retired at the next election."

Dr. Just Lucas-Championnière, surgeon to the St. Louis Hôpital, has been elected a member of the Académie de Médecine. Dr. Lucas-Championnière is as expert with the bicycle as he is with the knife.

SOME METHODS OF STUDYING CASES.

By GUY C. M. GODFREY, M.D.,

FIRST LIEUTENANT IN THE MEDICAL DEPARTMENT, U. S. ARMY.

For convenience I have divided this article into three headings, Value, Human Nature, and Analysis.

I. Value.—The study of a case is of twofold value, viz.: immediate and remote value. The immediate value consists in the value to the patient and to the physician. The patient receives the value of his protector's research, and the physician gets the credit of being well-posted, thoughtful, and successful.

The remote value is that which accrues to the physician himself, because it helps him in future cases and aids in the development and training of his own mind. Remember, there is a mental as well as physical training.

Continued thought and study on each case increases the element of success in that case. Increased success means increase of practice. Hence we have what I have termed a progressive value, which makes itself apparent mentally and financially.

If, in thoughtfully considering a case, you find you are not certain about the cause, the symptoms, etc., go and look them up in a text-book, and you will increase your professional knowledge and consequently your professional value. A physician is generally called to a case on account of his value, or, in other words, his ability to treat that case. The certainty of the diagnosis of a case is to a doctor what the knowledge of the position and numbers of an enemy is to the general commanding an army. It is true he may be defeated, but still he has a greater chance of victory.

II. Human Nature.—A knowledge of human nature is a great adjunct in studying a case. Fothergill has said that the successful man is the man who knows human nature as well as his profession. This rule holds good in our profession as in others. It is sometimes amusing and always useful to know when a patient is attempting to deceive you. I once knew an army-surgeon who was approached at sick call by a soldier desiring to be placed on sick-list. Now, as it happened, the surgeon had on the previous evening seen this soldier somewhat under the influence of liquor. The man claimed, however, that his back was sprained, but after examining him the surgeon doubted the truth of this statement. He turned suddenly to the patient and asked, "How did you sprain your back?" The man stammered out something about lifting some wood, but was interrupted by the surgeon exclaiming: "You are mistaken sir. You sprained your back carrying that load you had last night." The soldier returned to duty and never tried to shirk again.

The knowledge of human nature, or the analysis of character, is often useful in ascertaining the causes of disease. Patients often keep back a venereal history which it is necessary you should know, and by carefully scrutinizing the person while you question him you can tell, usually, if he is deceiving you or not. Then again the question presents itself as to whether this man is the kind that would deceive you. After carefully watching his hands, face, movements and appearance, you can generally arrive at a correct conclusion and base your ideas accordingly. A knowledge of the different temperaments and the diseases to which they are most liable, will aid you in forming a diagnosis. During the course of the disease your study of the case will enable you to govern yourself according to the temperament of the patient, and tell you how much to show your sympathy, hopes, or earnest thoughtfulness, or all combined.

The knowledge of character is an excellent aid in giving a prognosis. It helps by giving an insight into the mental and physical energy of the patient; by telling you the amount of that patient's self-confidence, will-power, and intelligence; and by informing you of the probability of his following your directions regarding rest, diet, medicine, or habits.

III. Analysis.—The inductive system of reasoning was devised by Lord Bacon, and consists of reasoning from cause to effect. It is the system of analogists. The deductive system is that which begins at a result, and successively establishes the causes. The inductive system assumes that if the causes are found to be correct, the result must be correct. Pure logic is the process of reasoning on abstract subjects. Applied logic is logic applied to the objects about us. Some men have natural analytical minds. All minds are improved by training. The value of reasoning power in medical men is obvious.

In medicine both the inductive and deductive systems are useful in the following ways :

1. From cause to symptoms. (I have included physical signs in with symptoms.) Example : In an extensive burn there will be a large number of nerve-terminals destroyed, a large surface formed which will be allowed to rapidly conduct heat and consequently energy from the body, therefore the shock will be great.

2. From cause to treatment. Example in preventive treatment : The cause of small-pox is a germ. Vaccine destroys or weakens that germ. Therefore we vaccinate. Example in curative treatment : The heart-murmur is caused by anæmia. Anæmia is the insufficiency of hæmoglobin in the blood. Iron increases the amount of hæmoglobin. Therefore iron cures anæmia.

3. From morbid anatomy to symptoms. Example : Knowing in a case of typhoid fever that Peyer's patches are inflamed, we will comprehend that if the bowel is ulcerated through at one of these points, a certain set of symptoms will appear.

4. From morbid anatomy to treatment. Example : In the second stage of pneumonia we know that the lung is wellnigh consolidated, and reason from that, that the circulation in that part of the lung is obstructed, and that more work is thrown on the heart. Therefore we conclude that we will promote resolution in the lung by cold applications to the chest, and stimulate the heart by the use of strychnine and alcohol.

5. From cause to morbid anatomy. Example : If a gun-shot wound has been caused by a large lead bullet, we conclude that there is a great amount of coagulative necrosis around the track of that wound, and hence we reason that the wound will most likely heal by granulation.

6. From symptoms to treatment. Example : The symptoms of a case indicate the beginning of an attack of apoplexy. We enjoin rest in the recumbent posture to lessen the heart's action, and de-ligate the extremities after Dawbarn's method, to keep as much blood as possible from the brain.

7. From treatment to symptoms. Example : If in a case of urethritis, we find after a few days' vigorous treatment that the inflammation has subsided, we conclude that it is a case of simple urethritis and not gonorrhœa.

8. From symptoms to morbid anatomy. Example : If a patient presents rapid, shallow breathing, cough, pain on inspiration, fever, and flatness on percussion over the lower part of the lung, we conclude that there is an inflammation of the pleura accompanied by serous exudate.

9. From symptoms to cause. Example : A case exhibits shock, stercoraceous vomiting, pain in the groin, etc., and we find that we have to deal with a strangulated hernia and not with what the patient thought was only an abscess.

10. From treatment to cause. Example : We are in doubt as to whether a certain ulcer is an epithelioma or syphilitic sore. If the latter, it disappears under strong doses of the iodide of potassium.

11. From the history of the case we induce various important features ; and from the cause, symptoms, and results of treatment we find many things corresponding with the history, which add to the confirmation of the diagnosis. All these methods produce proofs which are not merely added proofs, but proofs increasing in regular arithmetical progression.

All these methods are not needed in every case, nor can they always be reasoned out at the bedside ; but, they may occupy the mind of the thoughtful practitioner while indulging in his after-dinner smoke, or at any other time which suits his convenience.

On the two methods of induction and deduction, is based the *rationale* of therapeutics. Therapeutics is to the physician, and antisepsis is to the surgeon, what logistics and strategy are to the leader of an armed host.

METHOD OF TESTING FOR ALBUMINURIA.

By P. J. McCOURT, M.D.,

NEW YORK.

UNDER the above caption, in the MEDICAL RECORD of September 29th last, Dr. Philip Jaisohn, of Washington, D. C., points out a few—very few—of the illusions of the so-called tests in common use for albumin. That gentleman condemns some of these time-honored standards of proof on general principles, without specifying their individual features of weakness. Another test (clearly a perversion of Spiegler's), wherein grains, grammes, and cubic centimetres are all jumbled chaotically together in the same formula, is similarly disposed of, but especially because it is too sensitive, "the most delicate test known," and because it will detect albumin in the urine "in the proportion of 1 to 50,000." This decision is unfair to the test. Had the doctor doomed it because it will, like many others I have tested, detect "albumin" where albumin does not exist, he would have done justice to the test and rendered a substantial service to his readers. Again, if it be "a well-known fact," as Dr. Jaisohn and many others declare it to be, that normal urine contains albumin either during the period of digestion or any other period, except when the albumin is derived from pus or blood, I have been unable to verify that "fact," after the diligent search of years and ample opportunities. The so-called tests which were supposed to have detected albumin in the urine during the period of digestion were merely defective, and reacted on peptones, etc.

Dr. Jaisohn next proceeds to give us his favorite test, still another modification of the heat and nitric acid series, which he had just repudiated, and which modification presents few if any advantages over, and consumes more time than any of them. Fuming nitric acid, to which he still clings, is not a mild companion in the office, the pocket, or the sick-room ; and the tale it tells is quite as treacherous as the substance. The time required for this analysis will often forbid its employment, even when a test is urgently called for. To make the urine turbid, filter it, boil the filtrate, let it stand one-half hour, boil again, and then assume the effect is a tedious, clumsy task in hurried hours of office practice or at the bedside.

During several years past I have employed, for myself and a number of my professional friends, a modification of Mehn's test, as modified by Millard, consisting of

℞.	Acid. phenic. glac., ninety-five per cent..	ʒ ss.
	Acid. acetic. puri.....	ʒ j. ʒ vj.
	Add liquor potassæ.....	ʒ v. ʒ iv.

The glacial phenic acid should be reduced to the ninety-five per cent. solution at the moment of compounding, else the resultant fluid will be turbid ; and all ingredients must be chemically pure.

To 5 c.c. of urine in a test-tube add 0.5 c.c. of the test, slowly from a pipette, to underlie the urine. In the presence of albumin a white, milky ring, of varying depth and density, to a faint milky cloud, will give the qualitative and quantitative result.

This is an ideal test for albumin, so accurate, sensitive, and convenient as to meet every requirement. By its aid we can, in five minutes, take the specific gravity, reaction, and determine the presence or absence of albumin. The test will react with 1 to 300,000 of artificial albumin and water, and is not obscured by peptones, phosphates, urates, nitrate of urea, nor even by sugar. These merits are not possessed by any other test for albumin with which I am acquainted; and I am familiar with all. The exposure from frequent use will in time change its color from clear to light brown; but this change of color does not impair its delicacy. Having traversed this entire field, and tested nearly all the tests known to us in urinalysis, I have come to rely wholly on this one for albumin.

In examining the urine of women it should not be forgotten (as it too often is) that the best test we can apply is often valueless unless the parts are thoroughly cleansed before urination.

The ideal test for sugar is yet to be formulated. Purdy's is the best, but is not perfect. Fehling's test, which has been so long relied upon, is unworthy of the name, and a reproach to our science.

233 West Twenty-third Street.

Progress of Medical Science.

Hernia of the Bladder.—Dr. Rose has reported the case of a woman, aged twenty-four, who had been the subject of a hernial tumor for three years, and had been anæmic for a number of years. The hernia was reducible, but a truss had been worn until three weeks before the woman came under observation, when the hernia became so painful that the pressure of the truss was unbearable. Nine months previously there had set in pain on micturition, and at times the woman had gone twenty-four and thirty-six hours without passing urine; she had an impression that at these times the swelling always increased in size. Micturition had become so painful at times that she had to support the rupture with the hand to secure relief. An ovoid swelling, about an inch long and half an inch wide, was present in the left inguinal region, with its long axis in the direction of the canal, and extended downward and forward toward the centre of the left labium majus; there was a distinct though slight impulse on coughing, and at times the swelling became as large as a small hen's egg. When the patient had been gotten ready for operation and was anæsthetized, and was placed in a recumbent posture on the table, all trace of the swelling disappeared. An oblique incision about three inches in length was made, with its centre over the external abdominal ring, which was clearly defined, but no protrusion was found and no laxity of the abdominal wall felt. At this moment the patient fortunately vomited, and a small protrusion occurred through the external abdominal ring. This was drawn well down, and after clearing the fascia away it was incised. The wall was much thicker than was expected, and a few drops of a straw-colored fluid escaped, which proved to be urine, indicating that the cavity of the bladder had been entered. The wound was at once douched with a 1 to 40 carbolic lotion, and the vesical incision closed by a double row of fine catgut stitches, which included everything but the mucous membrane. During the necessary manipulations a second attack of vomiting caused the protrusion of a small swelling just external to the preceding one. On laying hold of this the peritoneal membrane gave way and a fine piece of omentum protruded. As this latter was somewhat extensive, it was ligated in successive portions and removed, the stump being returned into the abdomen. The peritoneal sac was now well drawn down, transfixed with catgut, and tightly ligated and cut away, the upper part at once retracting within the abdomen. Three deep sutures were now passed through the parietal wound and the canal closed, while the external wound was sutured and dressed in the usual way, a drainage-tube being introduced. After the patient had been put to bed a rubber catheter was tied in the bladder and the urine permitted to run off. The first few ounces that passed were blood-stained, but subsequently the secretion came away quite clear, twenty-one ounces being voided in the first fifteen hours. There was no vomiting, and the case progressed to convalescence without a hitch. The patient subsequently had one or two slight attacks of retention, although there was no return of the pain or discomfort previously complained of. The cicatrix in the groin became firm, and there was no return of the hernia.—*The Lancet.*

Extra-uterine Pregnancy; Elimination of the Fœtus per Rectum.—Dr. Spannochi reports the following case of extra-uterine pregnancy, remarkable for the mode of its termination. A robust woman, without a trace of disease of any kind, four months after a perfectly healthy labor, began to complain of pains in the hypogastrium. The symptoms pointed to an extra-uterine pregnancy, probably in the left Fallopian tube. A month later the sac ruptured, and the fœtus was discharged into the abdominal cavity. Reactive peritonitis around the foreign body came on; then followed suppuration and perforation of the intestine with discharge of pus. Owing to the continuous contractions caused by the presence of the foreign body, the intestine became dilated and prolapsed; finally, after twenty-eight days, the fœtus came away through the anus. After a considerable time complete recovery took place.

Cork Splints for Deflections of the Nasal Septum.—Dr. T. Passmore Berens reports excellent results from the use of a simple device for a splint in cases of fracture or operation for deflected septum nasi. The plugs of cotton or oakum become too readily foul, while the various supports which have been used have many disadvantages, the soft-rubber tubing being too yielding, while the hard-rubber or ivory plugs cause too much pressure and pain. Dr. Berens's device to overcome these and other difficulties is as ingenious as it is simple. He makes his splints from corks in the following manner: "A selected cork (pint-bottle size), in average length one and one-fourth inch, in breadth at its broad end three-fourths of an inch, at its narrow end one-eighth to one-fourth of an inch less, in thickness from one-fourth to three-eighths of an inch, is whittled to the shape of an almond with the point cut off, and flattened on the side that is to lie against the septum; the opposite side near its lower border is slightly grooved for the reception of the inferior turbinate body. A nasal burr or trephine is now used to hollow the splint, leaving the shell one-sixteenth to one-eighth of an inch thick. A rat-tail file, small-bladed knife, or red-hot metal may also be used for this purpose. Sandpaper is used to smooth both the inner and outer surfaces, and the whole splint is then coated with flexible collodion, to which has been added iodoform in the proportion of thirty grains to the fluid ounce, allowed to dry, and it is ready for use. The making of the splints requires no especial mechanical skill, and they can be modified with ease to suit the peculiarities of each case." The special advantages of these splints, which are possessed by no other similar device, are the quickness and ease with which they can be made and shaped to fit the peculiarities of each case; their cheapness, lightness, and elasticity, combined with sufficient firmness to support the septum; their durability and non-conduction of heat and cold, and non-interference with the free circulation of the blood; the ease with which they can be cleaned *in situ* by washing out with peroxide of hydrogen and boric acid solutions, followed by an oily spray, as benzoinol; and the length of time they can be worn without pain, discomfort, or severe ulceration.—*Boston Medical and Surgical Journal.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, January 12, 1895.

REFORMS IN THE DEPARTMENT OF PUBLIC CHARITIES AND CORRECTION.

IT is apparent that important changes are impending in the city departments. Several projects of reform legislation are designed to affect the character and composition of the several commissions, but probably that which will most certainly be realized, by legislation, will be the power of removal granted to the Mayor.

Among these departments that of Charities and Correction is so completely medical, in its character and work, that we cannot allow the occasion to pass without a word of comment on the interests involved in any changes in the *personnel* of the governing body. It is essentially the City's department of public hospitals. Of the 14,990 inmates of the institutions under the charge and control of the Commission, but 1,990 inmates are in the penitentiary and city prisons, leaving a total of 13,000 in the other, or hospital division, of the service. It is apparent, therefore, that six-sevenths of the duties devolving upon the Commission pertain to the management of hospitals.

These hospitals require for their efficient care and conduct a variety of skilled medical officials. In the several hospitals for the insane are upward of 6,000 patients, requiring a score or more of physicians qualified for the care and treatment of that special class. Hundreds of attendants, male and female, adapted to the care of the insane, must be selected. There are three large general hospitals, and four emergency hospitals, each of which must have its medical staff and corps of minor officials. There is a hospital for infants, another for epileptics, and an asylum for idiots. There are maternity hospitals, and an enormous out-door service and relief. From this imperfect statement we can estimate not only the vast amount of detail business required of the Commission, but how largely that work falls within the immediate sphere of medical duties.

It is evident that the principal business of a department thus devoted to the care and control of hospitals cannot best be administered by a body of layman. It will certainly transpire that incompetency, inefficiency, and wastefulness will characterize the management. Unable to form a correct opinion of the qualifications of the medical officers for their special duties, incompetent men will be appointed. Ignorant of the internal service of hospitals, the Commissioners have no personal judgment to guide them in estimating its defects. In the matter of supplies they must trust entirely to the honesty of others, and hence arises wastefulness. The inspection of such a body of officials has no significance whatever, and rather encourages than corrects vices in the conduct of the local officers.

The great want of the governing bodies of departments of charities is a membership of thoroughly competent physicians. The requisite qualifications of the medical members may be summarized as follows: 1. They should be of mature age and high reputation in their profession, that they may select officers judiciously and command the respect, not only of all of the medical officials, but of the profession at large. 2. They should have had large experience in all of the details of hospital management, in order that their own personal judgment may always control rightly and wisely all details. 3. They should be personally familiar with all of the institutions of the department. Physicians thus equipped for their position, should devote all of their time to these duties. They should regularly, or at short intervals, visit every hospital and personally examine the operations of every branch of the service.

Has not the tide of public opinion in favor of reforms in the management of the departments of the city government, risen sufficiently high to warrant the Mayor in giving us a model Commission of Charities and Correction? We believe it has, and that if he fails to select persons of eminent fitness for these responsible positions, there will be great disappointment. We speak only for the medical profession, and while we urge that the Commission shall be medical, at least as regards a majority of its members, we also urge that they be qualified for their duties. There are among the senior physicians of the city men of great respectability, who have had large experience in the public hospitals, and who would give their time to the duties of the office. We can mention the names of many physicians whose appointment would give ample assurance that the Department of Charities and Correction would hereafter rank among the best administered branches of the City Government.

ANTIVIVISECTIONISTS AND THE SERUM TREATMENT.

WE have been waiting for the antivivisectionists to put themselves in evidence in the matter of the horses who are being "poisoned" all over the world and subjected to what antivivisectionists call "diabolical tortures" in order to procure immunizing serum.

The pictorial organ of the humors of antivivisection in this town is so far discreetly silent. But England has spoken in the person of Lord Coleridge. He has appeared at the head of a deputation protesting against the appropriation of money by the city for the purpose of manufacturing antitoxin. His argument is that it is a misuse of the tax-payers' money; but behind it all is the profound philosophic feeling that it is wicked to prick a few horses in order to reduce the mortality from diphtheria among human beings fifty per cent.

THE NEW COLLEGE OF PHARMACY.

The opening of the new quarters for the College of Pharmacy in its magnificently equipped building in West Sixty-eighth Street, marks an important epoch in the history of pharmaceutical progress, not only in this city, but throughout the country. From 1829, when this college was founded, until the present, the scientific druggists of this city have labored to elevate the standard of educational requirements of pharmacists, and have in the end succeeded in creating a new and distinct profession, which is a worthy outcome of their long and honorable struggle. The medical profession, always in active sympathy with such laudable efforts, now hails with delight the final triumph of principles as dear to it as to its sister guild.

Medicine and pharmacy must necessarily travel on parallel lines, and always be close enough to each other to grasp hands for mutual encouragement. The progressive physician and the progressive pharmacist have common interests. And now that a permanent centre has been established, which not only comprises a school of pharmacy in its widest sense, but a home for all societies and interests associated with the progress of pharmacy, there is every reason for congratulation that a proper foundation has been laid for most substantial advancement in the art and science of drug compounding.

The possibilities of the future can in a measure be imagined by taking into account the remarkable progress made during the past few years, not only in the improved methods of manufacture, but in the remarkable multiplication of new and useful remedies. All this is due, or at least largely due, to the knowledge and skill of the pharmaceutical chemist, who has replaced nauseous compounds with elegant preparations which are almost triumphs of æsthetic tastiness and proofs of gustatory delight. The bolus of olden time, which would almost gag a horse, is now replaced by the alkaloidal pellet, so tricked in the livery of a confection as to deceive the most sensitive palate, and even quinine, the bitterest dose of all, sues for truce in a sugar-coated armor.

Medicine and pharmacy are now going through an evolutionary process which must in the end sharpen the outlines of their respective functions. The community of interests must always remain, although the methods of obtaining the desirable ends for each must necessarily differ. In the line of progress it is not difficult to imagine that there must eventually be two classes of pharmacists, one for the prescription business pure and simple, the other for the sale of proprietary articles and medical knick-knacks. While from a pharmaceutical standpoint the model physician will be he who never dispenses his medicines, the ideal pharmacist of the future will be he who never substitutes medicines or advice, who never repeats a prescription without an order, and who is always a legitimate and trusted interpreter of the prescriber's interests. The realization of such possibilities is by no means chimerical. In fact, it would seem to be prophetically assured not only by the work which the College of Pharmacy has already done, but what, under its present energetic management and its talented faculty, it can be capable of doing in the future.

DOCKING HORSES.

Our *Animal Friends*, in taking up the subject of "docking" horses' tails, assumes a task in which there is some merit as well as sentiment. It has collected a large number of statistics and opinions on the subject, which we presume are trustworthy, though antivivisection figures are proverbially peculiar. There have, we are assured, been 102 cases of lockjaw from docking reported in the year 1891 alone. The opinions of veterinarians which are submitted are of interest:

"There is no justification for docking, unless the tail is deformed or diseased."—*Professor Pritchard, Royal College of Veterinary Surgeons.*

"Docking horses is cruel, barbarous, unnecessary, and discountenanced by the profession."—*Dr. William L. Zuill, University of Pennsylvania.*

"The operation is one employed to meet the demands of fashion. It is needless, painful, and cruel, causing the animal much suffering, and depriving it of its only means of defence against flies and insects. In my opinion no language too strong can be employed condemning this cruel operation."—*Dr. Samuel K. Johnson, Chief Surgeon New York Veterinary Hospital.*

"I hope the day may soon arrive when veterinarians will refuse to perform the operation. With them, I believe, rests the solution of the problem whether or not 'docking will remain as it is, a useless, worthless, and inhumane mutilation.'"—*Professor A. Liautard, M.D., V.M.*

"Those who practise docking do it clandestinely and cannot justify their act. That docking, or the mutilation of the tail, inflicts much pain and suffering, cannot be denied. The structure involved—skin, muscles, nerves, blood-vessels, and bones—cannot be lacerated, and then seared with a red-hot iron, without causing intense and often prolonged pain."—*Dr. L. McLean, M.R.C.V.S.*

"Besides the cruelty which is acknowledged to be identical with the operation, there are reasons on the ground of physiology why the tail should be left entire."—*George H. Dadd*, "*Theory and Practice of Veterinary Medicine and Surgery*," p. 395.

"Such operations as docking, nicking, and ear-cropping of horses must be classed together as not only cruel in themselves (useless and painful operations are cruel), but which render animals less valuable."—*George Fleming, C.B., LL.D., F.R.C.V.S.*

The antivivisectionist, unfortunately, rarely inserts the dates or the context, or gives the faintest indication that there are merits on the other side. In this case, however, we doubt if there are any. Nevertheless, the practice of docking is apparently not in the least checked. Perhaps it is because the good cause has such bad advocates. People who protest in the same breath against fishing, making antitoxins, and docking horses, are regarded as somewhat weak-minded.

Semi-centennial of the Discovery of Anæsthesia.—The Harvard Odontological Society, in conjunction with the Harvard Dental Alumni Association, held a meeting on December 26th, for the purpose of celebrating the discovery of anæsthesia by Horace Wells, fifty years ago.

A HYPNOTIZED MURDERER.

The daily papers print specific accounts of the case of Anderson Gray, who was sentenced to death for the killing of Thomas Palton. Gray did not do the act, but, as is alleged, he placed one Thomas Macdonald under hypnotic influence, and compelled him to commit the murder. Palton and Gray were enemies, while Macdonald was said to be a farm-hand, and innocent of enmity or intentional crime.

If the facts are as reported, the case is one of peculiar importance and interest; and one that ought to excite more than ordinary discussion.

It is not believed, by medical men conversant with the subject, that hypnotism can really be used for criminal purposes in the way that Gray is supposed to have used Macdonald. The French trials, in which hypnotism has been brought forward as an excuse for crime, have so far failed to demonstrate the point, and we are not aware of any case before the present one in which such verdict has been found or such sentence pronounced. It is quite possible that a person of determined character might work on the fears or passions of a weak-minded man, and cause him to commit a crime. But it is not necessary to invoke hypnotism in order to explain such an occurrence.

OUR MEDICAL STUDENTS.

The *Journal of the American Medical Association* publishes some statistics regarding the increase in the medical students of this country which are truly alarming. In 1892 there were, it says, 15,330 students in 98 listed colleges, and a total of over 18,000 among the 117 colleges of this country.

In 1894 there were 17,701 medical students among the 98 colleges, and an estimated total of 21,186 students—despite hard times and decreased immigration.

As against this extraordinary number of embryo doctors, we find that in the United Kingdom there were in 1894 only about seven thousand (*British Medical Journal*) medical students, while in Paris the total for 1894 was 5,144, of whom 1,002 were foreigners. Making all due allowance for population, therefore, it is evident that the supply of medical students for the United States is at the very lowest three times as great as it is in Great Britain or France.

It is no wonder that medical men complain of hard times when competition must necessarily be so keen. We presume that a rather large percentage of American medical students fall by the wayside, or if they graduate fail to pursue their profession. It is at best hard to understand how 8,000 new doctors every year can earn a living. It is, in fact, becoming constantly harder for a young medical man to get a foothold. What he lacks in training at college he makes up for by long waiting after he gets his degree.

A Suggestive Advertisement.—The following advertisement appeared in a recent issue of the St. Louis *Post-Dispatch*: "To Surgeons and Foot-ball Players.—Metallic Splints, 21 pieces in case complete, never used, to be sold cheap. $15 for $9. Apply, St. Louis."

News of the Week.

Antitoxin Notes.—From the reports published on all sides it would appear that the cause of the antitoxic serum finds nowhere more sanguine support than in Holland. Subscription lists have been opened by the medical journals and the principal daily papers. The Committee of the Witte Kruis has added to its budget for next year a sum of 5,000 francs (£200), to enable Professor Foster, of Amsterdam, to prepare the serum in that city. The Leeuwarden Society for the Promotion of Public Health has sent a delegate to Paris to study in Roux's laboratory the preparation of the serum and the effect of the treatment in the children's hospitals. In Rotterdam £400 was subscribed by the public within a few days. In the Algemeene Handelsblad a horse is now undergoing immunization.

M. Roux has now one hundred and forty horses undergoing immunization. On and after January 1st, the authorities of the Institut Pasteur hope to be in position to supply the whole of France with serum. The impossibility of getting the serum in the provinces is causing an afflux of diphtheria cases to Paris, and the attention of the Minister of Public Works has been called to the danger to the public health involved in the transport of such patients in ordinary trains.

At the Royal Institute of Hygiene in Rome, which is under the direction of Professor Pagliani, two horses are now being immunized and will be ready to supply the serum in six or seven weeks. The municipality of Rome have also two horses ready for immunization.

Serum Antitoxin.—The *Law Journal*, December 15th, contains an article which states that provisional protection under the patent laws has been applied for and granted with relation to the production of the antitoxic serum.

To Administer the Antitoxin Treatment.—Two inspectors of the New York City Board of Health, Dr. Bensell and Dr. Huddleston, have been assigned by President Wilson to the special work of administering antitoxin in all diphtheria cases where private physicians may make demand on the Health Department for it. Dr. Huddleston is one of the bacteriological department's own inspectors, and Dr. Bensell has been connected with the Bureau of Contagious Diseases. Both men will give their entire time to this work. At present the bacteriological department has about one hundred and fifty doses of antitoxin on hand, and is manufacturing it at the rate of one hundred doses a week.

Discussion on the Diphtheria Antitoxin at the Berlin Medical Society.—The discussion of the paper on antitoxin by Dr. Hansemann, of which we gave an abstract in a previous issue, was begun at a meeting held on the subsequent week, December 5th (*British Medical Journal*). There was a very large attendance and a great deal of excitement and interest.

Von Bergmann was the first speaker. He denied Hansemann's assertion that the Loeffler bacillus was not to be found in every carefully examined case of real Bretonneau diphtheria. In 430 cases of diphtheria out of a series of 450 cases the Loeffler bacillus had

been found. In his opinion the Loeffler bacillus was undoubtedly the cause of diphtheria. He said that not without serious misgivings had he taken up the serum treatment. "A burnt child shuns the fire," he said; "and from tuberculin I had carried away bad burns." Three years ago Behring had tried to induce him to use the serum in his clinic; but he had then refused to do so, without having first seen successful experiments on animals. Behring had then experimented on a series of guinea-pigs. First he injected a Loeffler bacillus culture, and then treated a certain number with his serum. The results had been the reverse of encouraging; the guinea-pigs treated with serum all died, and the rest recovered. Of course, he (Bergmann) had then declined to use the serum. What induced him to make a trial of it much later was a conversation with Virchow, in the course of which the latter gave him the statistics obtained in the Kaiser and Kaiserin Friedrich Hospital. In view of these numbers and similar results in many other clinics, he thought it right to continue the trial of the new remedy, though a much longer space of time must elapse before he could give a final opinion of its therapeutic value.

After von Bergmann, Virchow rose. He said that treatment by diphtheria antitoxin was begun last March in the Kaiser and Kaiserin Friedrich Hospital. At that time Dr. Aronson had placed his serum at the disposal of the hospital—a present of the value of about four thousand marks—for which the hospital owed him sincere thanks. In June and July nearly all diphtheria cases were treated with the serum. The results were as follows:

In the first week,	cured	13;	deaths,	1 child.
" second	"	9	"	1 "
" third	"	6	"	2 children.
" fourth	"	12	"	1 child.
" fifth	"	6	"	2 children.
" sixth	"	1	"	1 child.
" seventh	"	3	"	0 "
" eighth	"	5	"	0 "

Suddenly the supply of serum ceased, as, unfortunately, the very horses from which the serum was taken died. The old methods of diphtheria treatment had again to be resorted to, and the results were:

In the first week,	cured	5;	deaths,	7 children.
" second	"	6	"	8 "
" third	"	6	"	6 "
" fourth	"	8	"	11 "
" fifth	"	8	"	5 "
" sixth	"	8	"	12 "
" seventh	"	13	"	6 "

This sad increase in the mortality induced the hospital to return to the serum, which was then procured from Höchst. Immediately there was a change:

In the first week,	cured	3;	deaths,	2 children.
" second	"	4	"	1 child.
" third	"	14	"	1 "
" fourth	"	14	"	2 children.
" fifth	"	17	"	1 child.
" sixth	"	17	"	5 children.

The total figures were as follows: In the whole space of time 533 cases were treated—303 with the serum, 230 without. The former had 13.2 deaths; the latter 47.8 deaths. Virchow continued that, in view of these results, he held it to be the duty of every doctor to use the serum in diphtheria. "All theoretical considerations," he added, "must give way to the brute force of these figures." He continued that, even if disagreeable by-effects were proved to occur here and there, they were not sufficient to dissuade him from continuing the treatment. Turning to the theoretical question, he said that he considered the disease artificially produced in animals by means of the Loeffler bacillus had nothing to do—anatomically—with Bretonneau's diphtheria. Nor did he consider the bacillus as the cause of human diphtheria. A theoretical explanation of the therapeutic action of the antitoxin serum must be left to the future.

Thus Virchow recommends the serum, to which he attributes a brilliant therapeutic action; at the same time he pronounces the theory which forms the basis of Behring's entire antitoxin therapeutics to be a fallacy.

In continuation of the debate at a meeting on December 12th, Dr. Bender stated that, as a result of his autopsical examinations, the diphtheria serum did not produce any direct action on the organs of the cadaver that could be recognized. Dr. Körte said that from a study of recent and old statistics he did not believe it true that the cases of diphtheria had become of a milder type. Dr. Gottstein called attention to the fact that the total mortality from diphtheria in Berlin had not yet been reduced as the result of the new treatment. Dr. Baginsky expressed himself as a strong believer in the efficacy of the serum treatment.

Results of the Antitoxin Treatment of Diphtheria at the Hôpital Trousseau.—MM. Moizard and Perrigaux report that, since September 18th, there have been 231 cases of diphtheria treated at the Hôpital Trousseau by antitoxin. The number of deaths was 34, giving a mortality-rate of 14.71 per cent.

The Dose of the Diphtheria Antitoxin.—Roux states that his practice has been to give 20 c.c. (over 5 drachms) of serum to each little patient on admission, and the same quantity, or half the same quantity, according to the severity of the case, twenty-four hours afterward; and if the pulse and temperature still remain high, the same dose is again given. He adds that the smallest quantity he has used has been over 5 drachms, and the largest quantity about 4 ounces; in one exceptional case he gave as much as between 6 or 7 ounces! Practitioners should remember these facts, and that Roux's series of cases is by far the largest and most important hitherto published.

Grip in New York.—Grip has made its appearance in this city and surrounding country. Seven fatal cases are reported by the Health Department.

Deputy Coroner.—Dr. Philip F. O'Hanlon has been appointed Deputy Coroner by Coroner O'Meagher, vice Dr. James E. Kelly, resigned.

French Hospital, New York.—Dr. George B. Fowler has been appointed Consulting Physician to the French Hospital, in place of Dr. Janeway, resigned.

New York Academy of Medicine.—At the recent annual election, held January 3, the following officers were elected: *President*, Dr. Joseph D. Bryant; *Vice-Pres-*

ident, Dr. W. M. Polk: *Recording Secretary*, Dr. Reginald H. Sayre; *Corresponding Secretary*, Dr. M. A. Starr: *Treasurer*, Dr. O. B. Douglas: *Trustee*, Dr. George L. Peabody; *Member of Committee on Admissions*, Dr. J. H. Fruitnight.

A Munificent Gift to the College of Physicians and Surgeons.—A gift of $350,000 has been made to the College of Physicians and Surgeons of this city, by Cornelius Vanderbilt, W. K. Vanderbilt, Frederick Vanderbilt, and G. W. Vanderbilt, to build an addition to the Vanderbilt Clinic at Amsterdam Avenue and Sixtieth Street, a part of the medical school, and the College of Physicians and Surgeons. This building will be fifty by one hundred feet and five stories high, fronting on Sixtieth Street. It will be used in connection with the Vanderbilt Clinic, and also in connection with the other departments, notably the department of pathology. Another building will be erected by virtue of this gift on Fifty-ninth Street, fifty by eighty feet and five stories high, for the department of anatomy. The addition of this building will be used in connection with the dissecting-room. Both this building and the addition to the Vanderbilt Clinic will be completely furnished and equipped by the donors. The two buildings are intended by the Messrs. Vanderbilt as a memorial to their father. Announcement is also made of a gift to the Medical School, from Mr. and Mrs. W. D. Sloane, of $200,000, for the enlargement of the Sloane Maternity Hospital, at Amsterdam Avenue and Fifty-ninth Street. The size of the hospital will be nearly doubled by this addition. Mrs. Sloane will completely furnish and equip the new building, has offered to provide for its maintenance during her lifetime, and will make suitable provision for it at her death. Plans for all these buildings are being made, and work will be begun on them as soon as the weather permits. They will conform to the style of the present buildings. The present gift by the Vanderbilts is a continuation of the munificence which they have shown toward the College of Physicians and Surgeons since the first gift of $500,000 was made by the late William H. Vanderbilt in October, 1884. The aggregate of the gifts to date from members of the family and from William D. Sloane, not including the amounts expended by Mrs. Sloane, over and above her endowment, to meet the operating expenses of the Maternity Hospital, is $1,970,000.

Monument to Charcot.—The pupils and former associates of Charcot in Paris and throughout France, are engaged in raising a fund for the erection of a bronze statue of him in the Salpêtrière. This movement is now receiving cordial and material support in Germany, in England, and in Italy. It has, therefore, seemed desirable to the neurological societies of New York and Philadelphia that the profession in America join in this testimonial as an evidence of the eminent services of Charcot in neurology and medicine. For this purpose the undersigned have been appointed a committee to bring the matter to the attention of the profession and to receive contributions, which will be duly acknowledged and forwarded to the central committee in Paris. It is requested that all who desire to contribute to the success of this undertaking send their subscriptions to the members of the committee nearest to them, or direct to the treasurer, Dr. C. A. Herter, 819 Madison Avenue, New York, before the first day of February, 1895.

Death of Dr. John Chapman.—Dr. John Chapman, who recently died at his residence in the Avenue de l'Opéra, was one of the best known members of the English colony in Paris. He was the author of several publications on medical subjects, chiefly relating to the treatment of cholera, sea-sickness, and other affections by the application of ice-bags to the spine. He was best known to the public, however, as one of the editors of the *Westminster Review*—a position which he held for a great number of years. In his earlier life Dr. Chapman was a publisher, and is thought to have been the last of the older generation who were booksellers as well as publishers, and stood behind their own counters. His business and his connection with the *Westminster Review* brought Dr. Chapman into contact with George Eliot and other literary notabilities. We believe it was in a kind of literary hostel or boarding-house near the Strand, kept by Chapman, that the author of "Romola" first met George Henry Lewes.

The Late Dr. Detmold.—Dr. Detmold was a unique and interesting figure among the surgeons of New York. Many will read with interest the following comment upon his career which appears in the *Evening Post:*

"Owing to his advanced age and active participation in events more than a half century ago, Dr. Detmold's professional career is peculiarly interesting, as illustrative of the growth of New York, as he was first located near the Battery, then a fashionable quarter, and afterward in Spring Street. His clinic, where orthopedic surgery was first introduced, was held in Mercer Street. When the New York Hotel, recently demolished, was first erected, his friends thought him reckless in taking an office there, as it was 'too far up town,' but as an extra fee was charged in those days for a visit above Fourteenth Street their fears were probably not realized. He was the pioneer of horseback riding here, which he kept up until his eighty-second year, after which he could be regularly seen in his carriage until within a few weeks of his death."

The Yale Faculty has decided to build a series of cottages for the reception of patients suffering with contagious diseases. They will be completely isolated, and will probably be constructed near the present Yale infirmary. Work on the cottages will begin at once.

Rabies in Mount Vernon, O.—A supposed rabid dog recently bit seventeen persons in Mount Vernon, O.

The Hotel Physician.—A hotel physician, who has evidently both candor and experience, gives this opinion of his kind of life to a reporter for *The Sun*. "Professionally speaking," he says, "the life of a hotel doctor is not pleasant. Financially speaking, it has its advantages. Just how some physicians attach themselves to hotels is peculiar. The doctors who do this seem to be averse to enduring the early struggles of a young physician. We have all heard of young physicians in the country who spend their last dollar in hiring carriages in order to wheel madly through the town with the hope of impressing the residents with the size

of their practice. There is method in such a course, and there is just as much method when a young physician in the city keeps his eye open for a hotel berth. As soon as this is found he gets together all his spare cash and hires a room in the hotel. He then gets permission of the proprietor to hang out his shingle. "In many cases physicians who started in early life with a hotel berth, merely to get transient patients and avoid the dull and heart-aching waits for practice, have continued on at the hotel until they are old men. Yet there is always a pang in their hearts. They are like many old bachelors who look around them and see their friends surrounded by happy families. There is a dull longing in the hearts of these old bachelors on such occasions. Just so the hotel doctor looks on his brother physicians with steady practice in families that have learned to regard them with fondness and esteem." The hotel physician paused in his story and then intimated that the great physicians of New York City were rather inclined to look down upon the men of the same profession who reside in the hotels, or at least upon those who have passed most of their days as hotel physicians. It is the advice of one of the oldest hotel physicians in New York City that young men starting in life would be far better off in the end if they took to the woods and built up a practice, instead of becoming hotel physicians and living in comparative ease and comfort, but without any of the real blessings of the profession.

"Sundown Doctors" in Washington Forbidden to Practise.—The Commissioner of Pensions has issued an order prohibiting Pension Office clerks from practising medicine. The explanation of this order is that a large number of men employed in the Pension Bureau hold diplomas as physicians, and have private offices where they attend to patients outside of office hours. These physicians are called "sundown" doctors, and for a great many years the medical profession outside of those who hold Government jobs has been antagonistic to them. Year after year attempts have been made to have the "sundown" doctors either give up their Government salaries or their private practice, but until now no argument could be found weighty enough to be sustained by the officials in authority. Investigation since the small-pox epidemic has demonstrated to the satisfaction of the Commissioner of Pensions, however, that contagion has been carried by the "sundown" doctors from their patients to their fellow-clerks in the departments, and the long-sought-for order has been issued. It is said to be a fact that all of the many cases of small-pox that have existed in Washington recently, and many of which proved fatal, are directly traceable to contagion brought to the Interior Department by a clerk whose child, while suffering from small-pox, was treated for chicken-pox, and buried under a certificate that she had died of the latter disease.

Pasteur.—The Paris Municipal Council has decided to rechristen the Rue d'Ulm and to give it the name of the illustrious *savant* M. Pasteur. The venerable scientist is said to be in very bad health.

A National Diphtheria Commission.—According to the *Journal of the American Medical Association*, Representative Goldzier, of Illinois, has prepared and will endeavor to secure the prompt adoption of a joint resolution for the creation of a National Commission for the investigation of the antitoxin treatment of diphtheria.

A Veterinary College is to be organized at San Francisco, Cal.

Diphtheria at the Mount Vernon Branch of the New York Infant Asylum.—Since the end of September diphtheria has prevailed to a considerable extent at the Mount Vernon Branch of the New York Infant Asylum, and it was found necessary to set apart three of the cottages at the institution for those suffering from the disease. Up to the present time there have been over eighty cases and about sixteen deaths. Recently antitoxin has been used in the treatment (a portion of the supply having been obtained from Berlin and a portion from the New York Pasteur Institute), and, while the number of cases thus treated is not large, no death is said to have occurred among them.

The Value of Nuclein and Nucleinic Acid.—Dr. Victor Vaughn gives this very modest statement of the therapeutic value of nuclein and nucleinic acid (*Medical News*). After confessing that it is practically useless in advanced phthisis, he says: "In initial cases of pulmonary tuberculosis, when there is no secondary infection, and when the area involved is small and the resistance of the patient not too much reduced, the proper employment of this agent may produce at least a temporary cure. I say 'at least a temporary cure,' because none of these cases has been under observation a sufficient length of time for me to say that the bacilli will not reappear. In the few cases of urinary tuberculosis that I report in this paper the results have been remarkably satisfactory. The results that I have secured so far encourage me to continue the work. . . . I must not close this paper without mentioning another point: I am convinced, especially from my experiments on animals, that nucleinic acid, improperly used, may do harm. It acts, as I have elsewhere shown, by stimulating the organs that elaborate the polynuclear corpuscles, and these may be over-stimulated. Nucleinic acid fails to be of service unless these cell-forming organs respond. They may fail to respond on account of lowered vitality, or they may be paralyzed, as it were, by an excessive dose of stimulant. The agent is not one to be used indiscriminately. Already some physicians are supplying tuberculous patients with hypodermic syringes and solutions of nucleinic acid, and telling them to go ahead and treat themselves. Such practice as this may make the study of this subject result in a misfortune."

Suit Against the British Medical Journal.—It is said that Dr. Stretch Dowse is about to enter an action for slander against the *British Medical Journal*, and that he will claim £5,000 as damages. In the sensational articles on massage recently published in the *British Medical Journal*, Dr. Dowse's name was mentioned as one of those who give certificates for proficiency in massage.

The Disinfection of Medical Fees.—Professor Demosthenes, of Bucharest, according to the *Bulletin Medical*, calls attention to the danger of the transmission of

contagion by fees received from patients suffering from contagious diseases. He contends that such money ought to be kept in a pocket-book of metal or impermeable cloth, which can be sterilized by the flame or by boiling, and that the physician ought to disinfect his hands before leaving the sick-room.

A Pasteur Institute at Algiers.—Thanks to the energy of Dr. Trolard and to the liberality of the Governor-General of Algiers, an antirabic institute, which is to bear the name of M. Pasteur, was opened in Algiers on October 1st. On the very day of opening a woman and a child, who had been bitten by stray dogs, were brought to the institute for treatment.

Lady Foot-ball.—Woman seems now to have a task before her in which we fear greatly she will fail. Report goes that female foot-ball teams will shortly contest in public, and the problem is now, on the one hand, to make the performance graceful, and, on the other, not to spoil the game. Those who have witnessed the modern developments of that noble sport will probably doubt whether even women will be able to harmonize such conflicting aims. Into this question we will not enter. Whether the real game played by women is a graceful or a disgraceful sight, Mrs. Grundy must decide, and whether the game played in a ladylike manner is worth looking at, will doubtless soon be settled by the polite frequenters of the foot-ball field, who, we may be sure, will not be backward in expressing their opinion. In the meantime, we enter our protest against the whole performance.—*British Medical Journal.*

Obituary.

HENRY GOLDTHWAITE, M.D.,

NEW YORK.

Dr. Goldthwaite died suddenly last Thursday morning, in his office at the Fifth Avenue Hotel, the cause of death being apoplexy. He was born in Mobile, Ala., April 13, 1842. He was the son of Judge Henry Goldthwaite, of the Alabama Supreme Court, and Eliza Witherspoon, member of the well-known Witherspoon family, of which John Witherspoon, a signer of the Declaration of Independence and a former President of Princeton College, was a member. He was a nephew of Judge George Goldthwaite, Chief Justice of the Alabama Supreme Court, and United States Senator from Alabama, and John A. Campbell, Justice of the United States Supreme Court; great-grandson of William Graham, at one time Secretary of the Navy, Governor, and Representative in Congress from North Carolina. He graduated from Princeton College in 1860. Entered the army of the Confederacy as a private, leaving the service at the close of the war with the rank of major.

After the war he was the Southern representative of Brown Bros., with an office in Mobile, Ala. In 1876 he was graduated from Bellevue Hospital Medical College, and served eighteen months as an interne in Bellevue Hospital.

He was one of the most noted and successful quiz masters in this city for a number of years, and was until recently connected with the faculty of Bellevue Hospital Medical College as an instructor. He was also one of the visiting physicians to the City Hospital.

He was a member of the County Society, New York County Medical Association, Society of Alumni Bellevue Hospital, Member of the University Club, and New York Athletic Club.

He was twice married, his first wife was a Miss Tarleton, of Mobile. In 1889, he married Mrs. Cornelia C. Munson, of Utica, N. Y., who with two children by his first marriage, survive him. Dr. Goldthwaite, in his official capacity as resident physician of the Fifth Avenue Hotel, was one of the most widely known men in the country, and numbered many of the nation's celebrities among his clientèle. He was a most genial and kind-hearted man, and was a veritable encyclopædia of interesting reminiscences.

The Late Dr. George A. Peters.—At a meeting of the Board of Trustees of the New York Physicians' Mutual Aid Association, held on the 11th ult., the undersigned committee was appointed to formulate and publish appropriate expressions of sorrow on the death of Dr. George A. Peters. In accordance with this authorization the following preamble and resolutions were adopted:

Whereas, This Board of Trustees has learned of the recent demise of Dr. George A. Peters, who was for many years a member of the Association and of the Board of Trustees, and for five years its President, taking at all times a deep interest in its success and welfare; therefore,

Resolved, That this Board herewith places on record its profound sense of loss to the Board, the Association, and to the profession, in the death of one of its most honored ex-Presidents.

Resolved, That this Board extends its sincere sympathy and condolence to his only child, Mrs. H. H. Chittenden.

Resolved, That these resolutions, signed by the President and the Secretary, and by the Committee, be published in the Medical Record and the *Medical Journal.*

(Signed) Daniel Lewis, *President*,
James E. H. Nichols, *Secretary*,
M. Blumenthal, David Magie, Charles E. Hackley, } *Committee on Resolutions.*

New York, December 18, 1894.

The following resolutions were adopted by the Board of Managers of St. Luke's Hospital, December 28, 1894:

On December 6, 1894, died, in a ripe old age, and after a life of active usefulness, the President of the Medical Board, George A. Peters, M.D. Dr. Peters was a member of the first Medical Board, organized March 1, 1859, for service in St. Luke's Hospital, and has been actively connected with it ever since. He served for over twenty years as Attending Surgeon, and for fifteen years as Consulting Surgeon, giving thus freely his conscientious service and best skill for over thirty-five years to the patients of this hospital. Others gave money for the support and development of this charity—he gave the service of his life; and none who were associated with Dr. Peters in his work will ever say that his gratuitous service to the very poorest of the patients of this institution was less painstaking or conscientious than that rendered to the wealthiest patients in his private practice. His was a unique personality; of strong convictions, of steady purpose, of practical sense, of ready wit, of intense reality.

The Managers of St. Luke's Hospital record upon their minutes, and order published, this tribute of their appreciation of his character, and of gratitude for his service. They also order that the resolutions of the Medical Board, and this resolution of the Board of Managers, be engrossed and sent to the family of Dr. Peters.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, December 6, 1894.

D. B. St. John Roosa, M.D., President, in the Chair.

Committee on Cancer.—In accord with a resolution passed at the last stated meeting, the President appointed the following committee on the investigation of cancer: Drs. J. D. Bryant, R. F. Weir, A. Jacobi, G. F. Shrady, T. M. Prudden, L. S. Pilcher, and H. M. Biggs.

"The Transactions."—On motion, the Council was given permission to publish the volume of "Transactions" as usual.

The Library.—Dr. George Thomas Jackson reported an addition to the library, since the last report, of fifty volumes, over two thousand medical journals, and a number of pamphlets.

The Treatment of Diphtheria, Including Serum Therapy.—Dr. H. W. Berg read the paper. (See p. 33).

Dr. W. H. Park said, referring to the bacilli shown on the screen by the author, that we recognized bacilli of true diphtheria which were virulent, and others which were not virulent, and resembling these, but differing from them in their mode of staining and in their more regular outline, were the bacteria of pseudo-diphtheria. It was true that in the early stages we might be in doubt regarding the diagnosis of diphtheria, but we saw many cases which we felt positive were cases of true diphtheria before making culture examination. In laryngeal cases it was best to assume that the condition was true diphtheria, even though diphtheritic bacilli were not found.

Prevention.—Regarding the prevention of diphtheria, he said health inspectors had reported many instances where the disease had been spread by allowing the sick to come in relation with the well too early after convalescence, especially before the bacilli had ceased to exist in the throat. Another important source of infection arose from members of the household departing elsewhere immediately upon learning of the presence of diphtheria in the family or house. An instance was cited of spread of diphtheria in this way, from a single case in a Long Island town, to different cases widely separated. Favorable reports had been made with regard to the prevention of diphtheria by inoculation with a small dose of antitoxin, which appeared to give immunity against infection for several weeks. In the treatment of true diphtheria he believed that most of us had come to the conclusion that it was non-irritating cleansing that was most important, antisepsis being less vital. All hope of killing the bacteria had been about abandoned, as the attempt would irritate the membrane and first kill the living cells and the patient. Regarding calomel fumigation, children's throats showed the bacilli just as long when it was used as when not, so that whatever value it might possess depended upon something else than the antiseptic influence.

From the few cases in which Dr. Park had seen antitoxin used, he concluded that it was a valuable remedy. It could not be judged by experience with tuberculin, since the latter when first introduced was a secret remedy and a dangerous one, while the nature of antitoxin was known to all and it was perfectly harmless. Being costly, spurious and perhaps dangerous preparations would be put on the market by irresponsible parties. The strength, or amount, of antitoxin contained in the serum should always be the guide to dosage, and not the amount of serum alone.

Bichloride Harmful.—Dr. Joseph E. Winters said it required bichloride of strength of 1 to 1,000 to kill the Loeffler bacilli, with exposure of two hours, which meant that it was an impracticable antiseptic in diphtheria. Moreover, it was positively harmful even in weak solutions, 1 to 4,000 causing irritation, and at times producing constitutional symptoms. Calomel fumigation was objectionable on the same grounds, while the benefits attributable to it in the way of stimulated secretions and ease of breathing could be much better obtained from inhalation of sulphurous acid vapor.

Hot Water Lotion.—The object of local treatment in diphtheria was not to destroy the bacilli, nor to remove the pseudo-membrane, as attempts in this direction would result in harm; it was rather to allay irritation and to wash away septic products. This could best be done with hot water or hot normal salt solution, say of a temperature of 140° F. Nothing else would give as much relief where there was much swelling and obstruction. Moreover, if it was possible for any local application to exert a germicidal effect, hot water would do it. A temperature of 140° F. would kill Loeffler bacilli, but of course the irrigating fluid of 140° had lost some of its heat by the time it reached the throat.

Regarding cleansing the nose by irrigation, Dr. Winters claimed that the plugs of membrane could not be removed by the fountain syringe. It was necessary to use the Davidson or more forcible hand syringe.

The Tent Condemned.—Dr. Winters condemned the method of enclosing the patient's bed by a tent, and said the harm from the stuffy atmosphere would more than offset the benefit from the steam or medicated inhalation. Without the tent the inhalation could be kept up indefinitely, without exhausting the patient. The use of bichloride internally had originated with the idea that it might act as a germicide, and it should no longer be countenanced. The germs did not enter the circulation, and the bichloride would have no influence on the toxin which was producing the constitutional symptoms.

Severe Cases Due to Mixed Infection.—Dr. J. W. Brannan said, with regard to predicting whether a case of diphtheria would prove mild or severe, that Roux had shown that the mortality in cases of diphtheria due only to the Loeffler bacillus, varied from five to ten per cent., while in those showing along with this bacillus also the streptococcus and staphylococcus, the mortality was seventy-five or eighty per cent. It seemed to Dr. Brannan that it would be well to bear this fact in mind in making tests and compiling mortality statistics. Regarding the death-rate in Willard Parker being lower than in European hospitals, he thought it might be accounted for by the fact that Willard Parker admitted patients of all ages, whereas, in Europe, the statistics had been taken from children's hospitals, and it was known that in infants the death-rate from diphtheria was greater.

Dr. A. Caillé had treated sixteen cases of diphtheria the past three months with antitoxin, showing the Klebs-Loeffler bacillus and being of severe nasopharyngeal type. Two had died, a mortality-rate in harmony with results obtained in Europe from this treatment, in severe and undoubted cases. Speaking of what we might expect from this treatment and what not, he said we could expect a specific effect in diphtheria from Klebs-Loeffler bacillus, but not in severe cases of mixed infection; we might expect immunizing power, such as had been claimed. It would be absurd to expect recovery in cases of heart failure or severe complications. Stimulants and irrigation with normal salt-water solution were also required.

Dr. C. A. Leale practised forced feeding by a soft rubber tube introduced through the nostril into the stomach and food injected with a hand syringe.

Dr. Fischer said he had treated 112 cases of diphtheria with antitoxin, 60 of them in this city, with a total mortality of 4, and it was his impression the mortality might have been less had the cases been selected as they ought. It should be used only in pure and simple diphtheria. Moribund cases should be excluded.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Adjourned Annual Meeting and Stated Meeting, November 26, 1894.

SENECA D. POWELL, M.D., AFTERWARD EGBERT H. GRANDIN, M.D., IN THE CHAIR.

Report of the Counsel for the Society.—The report of R. C. TAYLOR, ESQ., Counsel for the Society, was read by DR. FREDERICK PETERSON. Since it had been declared by the courts that only civil suit, not criminal, could be brought against those who had registered illegally as practitioners of medicine, it had become more difficult to reach this class of offenders, and the fines were too low for the expense incurred in prosecution. Nevertheless, seventeen cases had been brought before the courts, and those which had been tried or settled had proven successful. The judges, for specious reasons, seemed to show greater leniency toward offending druggists than others.

The County Directory.—DR. DANIEL LEWIS, editor of the "Medical Directory," read his report. It showed a steady increase in size (294 pages at present), in subscribers, in membership of the Society, in usefulness through new matter, including the "Directory of Kings and Westchester Counties." The expenses had, of course, been greater, still there had been a profit of $327, the total income having been $2,341.

Address of Dr. Powell.—The retiring President, DR. POWELL, thanked the members for their uniform courtesy and support during the year, and congratulated them upon the growth and work of the Society. The membership in 1880 had been 789; in 1894 it was 1,365. Some years ago, when Dr. Ellsworth Eliot was secretary, he had thought it proper to make a note of the fact that there was a lady member present. To-day there were on the list of members 39 ladies.

The new by-law, forbidding members recommending medical legislation which had not first received the sanction of the comitia minora and Society, might appear to some presumptuous, yet it was undoubtedly in the interests of the Society and of the profession whose sanction it had received.

Although the dispensary abuse still flourished, there was reason to believe that it was diminishing, because of sentiment properly directed against it. The President had not exercised his power to appoint a committee of five to confer with a similar committee from the Bar Association, with regard to a change in the matter of expert medical testimony in the courts, for the reason that the political atmosphere had not seemed favorable during the year.

Dr. Powell scored Governor Flower for vetoing the bill, which was simply intended to restore the punishment for the illegal practice of medicine, this penalty provision of the law regulating the practice of medicine having been, apparently by accident, omitted from the new codification. Thus we were virtually left without a vestige of a law against charlatans, abortionists, and those whose sole business was to dupe and injure the public. The County Society should frown upon advertising in newspapers and in other ways derogatory to the profession.

Inaugural Address.—DR. GRANDIN pledged to the Society which had so highly honored him his full power toward the safe guarding of the rights and privileges of every member, and toward the scientific cultivation and diffusion of medicine. We were here in the dual capacity of physicians and citizens, for our aims included not alone the relief of suffering, but also prevention of disease. He therefore dwelt a few moments upon certain matters which concerned the welfare of the Society and community.

During the administration of his predecessor it had been frequently necessary to remind certain members of the following by-law: "It is contrary to the dignity and interests of the medical profession for any member thereof to affix his name to any certificate, circular, or advertisement of any drug, nostrum, mineral water, wine, or other proprietary article intended to be used as a medicine or remedy in disease, or to any patented instrument or appliance that is intended for medical or surgical use."

Giving a certificate could not benefit older members, while it started younger ones on the wrong road in professional life. From every stand-point, therefore, it became the duty of the Society to enforce this by-law in order to maintain our own self-respect and that of professional men and laity who were not fellow-members. In the future let manufacturers do their own advertising, and we would silently test their products.

There were certain changes which it was desirable to effect in the laws in the interest of the laity and profession, and the members should exert their individual and collective influence, which was greater than many of us supposed, toward their adoption. In this line mention was made of the coroner's system, which should be abolished, as permitted by the new constitution, in favor of a system which the medical profession ought to have the privilege of drafting. Influence ought also to be directed toward the abolition of the law, which was of doubtful constitutionality, prohibiting a physician from occupying the position of president of the Board of Health.

Abortionists and Quacks.—The great general public, the power behind the throne in this country, should be made to understand where the responsibility lay for the failure of the Legislature to enact laws which would enable medical men to properly protect the public health, to drive out of the city and the State arrant quacks, to send notorious abortionists to prison, if not to the electric chair. Owing to the exercise of the veto power at Albany the past winter, our hands were tied; still must the public press be allowed to print suggestive advertisements; still, at frequent intervals, must the daily mail of even physicians contain the cards of notorious and unpunished criminals — for such, not to mince words, they all were. The time had come when we should stamp with our words, as all along we had done by our deeds, our utter abhorrence —from the stand-point of fathers, brothers, citizens, and physicians—of fœticide.

Bi-monthly Reports of Committee on Hygiene Suggested.—DR. GRANDIN suggested bi-monthly reports from the Committee on Hygiene on matters near to the public heart. The sanitary condition of the streets of this great city was often simply a disgrace to our boasted civilization. Then there was the question of street noises, with their untoward influence on the sick as well as the sound; the belching of smoke from the chimneys of powerful corporations; the senseless method in vogue of collecting street sweepings and garbage and their ultimate disposal; such and similar questions were of too great import to be briefly summarized in a report at the end of the year. By more frequent brief reports the public would be constantly reminded that this Society had an ever-present solicitude for the sanitary condition of the city.

It was suggested that if the Governor intended to appoint another health officer for the port of New York, it would be proper for the County Society to endorse some candidate who commanded the respect both of the profession and public. It would thus prove to the citizens that the County Society was ever ready to advise in matters which concerned the health of the community, as it was its right and privilege to do.

Misplaced Charity.—He had been asked by a number of the younger members of the Society to make a further attempt to draw the attention of boards of managers of certain of the metropolitan hospitals and dispensaries to the extent toward which they were giving medical assistance to other than the worthy poor. Although he had given the matter much thought, he had to confess the remedy had not suggested itself. Whatever it might be,

it lay in the hands of the managers, for medical men could not appear in the foreground in the solution of a matter which had apparently a selfish end. The managers should investigate the worthiness of all applicants, and reject the well-to-do and those of moderate means.

Committees.—The President then appointed the following committees: *Hygiene*, Drs. George B. Fowler, Clément Cleveland, R. W. Wilcox, Simon Marx, Edward N. Liell; *Ethics*, Drs. Edward B. Bronson, J. A. Andrews, Frederick M. Warner, H. C. Coe, C. S. Cole; *Prize Essays*, Drs. Robert A. Murray, W. Gilman Thompson, J. Clifton Edgar; *Auditing*, Drs. A. M. Jacobus, Herman L. Collyer.

Prevention and Treatment of Ophthalmia Neonatorum.—Dr. Charles H. May read the paper, the purpose of which was to show that the legislation of September, 1890, had not been effectual in reducing ophthalmia neonatorum and blindness in New York, and also to suggest a better law, one which would at least make it exceptional for blindness to occur in one or both eyes from the disease under consideration. He suggested that this Society appoint a committee to draft a suitable bill for presentation to the Legislature.

Dr. D. B. St. John Roosa thought there was no department in medicine in which there was as much unanimity on principles as in ophthalmology. This was noticeable in the treatment of purulent corneal inflammation, although some might use nitrate of silver, some a simple astringent, as alum, others only cleanliness. If the case were seen early the results were most gratifying, and ulceration of the cornea was almost unknown. He was unable to see why enforcing the law of 1890 should necessarily reduce the number of cases of ophthalmia neonatorum appearing at the clinics, for the very object of that law was to bring out those cases which hitherto had been kept in hiding by midwives and others. It was possible we might reduce blindness due to ophthalmia neonatorum by spreading information among practitioners and midwives as to the advantages of the method which had given such excellent results at the maternities. Let us not, he said, attempt to feed these people who were unable to feed themselves, with anything else but a spoon.

Dr. Herman Knapp thought the present treatment, although he had adhered to it with zeal, was laborious and not altogether satisfactory. The contagiousness of ophthalmia seemed to depend upon the freshness of the virus. At any rate ophthalmia neonatorum was infinitely less dangerous than the gonorrhœic ophthalmia of adults. It was an old gonorrhœa in the mother which infected the child, and in most cases it might not be the gonococcus of Neiser; it might be only an inflammation resembling gonorrhœal ophthalmia and not really such. He employed local sterilization, say by tincture of iodine, of infective corneal ulcers. Maintenance of the general health was exceedingly important in their cure.

Use of Nitrate of Silver a Needless Cruelty.—Dr Thomas R. Pooley thought the paper was sufficiently orthodox. His own view was that infection causing ophthalmia neonatorum did not occur until the child was born, for until that moment the eyes were firmly closed. After birth the first thing the infant did was to squawk, then to poke its hands into its eyes. Thorough irrigation of the vagina should be practised before labor to prevent infection getting on the hands; afterward observe strict cleanliness, and ophthalmia neonatorum would not arise. He believed it was needless cruelty to instil a one or two per cent. solution of nitrate of silver into the baby's eyes. Perhaps we would have more respect for it if some one would kindly instil some of the solution into our own eyes. He believed Credé's method might just as well be put aside. Nitrate of silver was often used too early also in purulent ophthalmia, and thus gave rise to a false diphtheritic membrane. Do not use cotton in cleansing the eye, but water. Boracic acid was much more preferable than sublimate solution. He agreed with the author that reports from midwives, and also from physicians, should be made to the Board of Health, and the latter should see that the law was enforced. Moreover, there should be a city hospital for the reception of cases of purulent ophthalmia, under the jurisdiction of the Board of Health and the care of ophthalmologists and trained nurses.

Children of Primipara Oftenest Affected.—Dr. W. F. Mittendorf said, among other things, that in his practice sixty-five per cent. of cases of ophthalmia neonatorum had occurred in the first-born, a midwife having usually been in attendance. He impressed the danger of infection of attendants when cleansing the infant's eyes, and had known one young physician to lose an eye in that manner, and give up the practice of medicine in disgust. A warm appeal should be made for antiseptic midwifery.

Dr. J. A. Andrews thought the statement that ophthalmia neonatorum was much milder than gonorrhœic ophthalmia in the adult was somewhat misleading. The difference was due largely to the fact that the tissues in the child were more resisting. Cleanliness was very important. Nitrate of silver was useful, but in the way it had been used it had destroyed many eyes. As a preventive he would not use Credé's method unless the mother had a discharge.

Dr. Emil Gruening thought as many eyes were destroyed by too little treatment as by too much. He instructed the nurse never to touch the upper lid nor the eye in cleansing, nor for any other purpose. Pressure upon the bone below would open the lower lid without injury to the ball. Some said use ice, others warmth, but really neither was very necessary, for the lid itself was a poultice. What was required was removal of matter in such a way as not to injure the cornea.

Dr. E. A. Tucker, of the Sloane Maternity, thought there had been overwhelming cumulative evidence in favor of the Credé method. Cleansing the vagina might be well enough if the patient were long enough in the hospital, which was not the case at the Sloane Maternity; yet during four years' stay in that institution he had scarcely seen one case of ophthalmia neonatorum—nothing more than a slight ophthalmia here and there about the eighth day, from the mother putting milk into the baby's eyes, or from the latter's dirty hands. The custom was, after birth of the infant, to drop one or two drops of a two per cent. solution into the eyes. Allow it to remain a fraction of a minute, then wipe it away.

Dr. May, in some closing remarks, also expressed the opinion that statistics were too strongly in favor of Credé's method to justify dispensing with it in infirmaries and tenements.

A motion was adopted, instructing the comitia minora to consider the propriety of drawing up a bill, requiring midwives and physicians to report cases of inflammation of the eyes in the newly-born to the Board of Health, the comitia to report back to the Society.

An International Congress on Childhood will be held in Florence in the spring of 1895. Among the questions to be discussed are, the physical, moral, and mental elevation of children, children's hospitals, the care of deaf-mute and blind children up to the time of their admission into an educational institution, care of poor and abandoned children, reformatories, and vagabondage in its relation to childhood.

Taxing Betting for the Benefit of Hospitals.—The French Government compels a certain proportion of the money made by betting on horse-races to be paid into the treasury for the benefit of the public charities. The hospitals last year received about $50,000 from this source.

MEDICAL AND CHIRURGICAL FACULTY OF MARYLAND.

Semi-Annual Meeting held at Cumberland, Md., November 21 and 22, 1894.

FIRST DAY—WEDNESDAY, NOVEMBER 21ST.

THE Medical and Chirurgical Faculty of Maryland convened in session in the Council Chamber of the City Hall, at Cumberland, at 10 A.M. After the address of welcome by Dr. J. M. Spear, and the address by the President, Dr. R. W. Johnson, the first paper was read.

Distention of the Stomach.—This was a paper by DR. H. SALZER, in which he spoke of the methods of diagnosis of diseases of the stomach, and especially distention of that organ, by examination of the gastric secretion. He did not always use the stomach-tube, but let the patient vomit the substance taken and then made an examination. He referred to the relaxed conditions of the abdominal muscles with movable kidney. The kidney was almost always palpable. He attributed this trouble to evils of dress and frequent pregnancies.

DR. WILLIAM OSLER thought that the method of Dr. Salzer was more pleasant than the one by the use of the stomach-tube. He thought that the examination for movable kidney, as suggested by Dr. Salzer, was important. He generally found signs of dilatation of the stomach in neurasthenic patients, and palpable, if not movable kidney, and it may be at times floating kidney. He believed in the abdominal bandage after pregnancy, and it was important in preventing these troubles.

DR. GEORGE J. PRESTON thought that all those who saw many cases of neurasthenia would be interested in this paper. It is a question how far the nervous condition affects the distention, and how far it ought to be treated. In many cases that he had treated he had noticed diminished knee-jerk.

DR. E. M. SCHAEFPER would support what he had said about the corset and absence of exercise. He thought the use of the tight corset was potent to do much harm, and exercise would correct many troubles, and he approved of the bicycle in certain cases.

Some Suggestions as to the Treatment of Wounds, Involving at the Same Time the Lens and the Ciliary Region.—This was the subject of a paper by DR. ROBERT L. RANDOLPH, in which he reported two cases where he did not find it necessary to remove the eye, but took out the lens, and one case recovered with some vision.

DR. HARRY FRIEDENWALD read a paper on the "Removal of Particles of Steel from the Interior of the Eye with a Magnet." He related several cases successfully treated and showed the magnet and explained the manner of using it.

The Diagnosis and Treatment of Diphtheria.—DR. WILLIAM H. WELCH made some remarks on this subject. The study of the antitoxins is the order of the day. The evidence that the Klebs-Loeffler bacillus is the cause of diphtheria is very conclusive ; no one can doubt this now. It is constantly present in every case of genuine diphtheria ; isolated in pure culture it is productive of the disease, and the disease can be produced experimentally in no other way. We are familiar with the toxic principle of this disease, and we know its physiological but not its chemical properties. This substance has been found in the body of those dead from diphtheria. There is probably no organism the study of which has led to such practical results as this. It gives us the diagnosis, prognosis, and treatment. The diagnosis can be made with certainty by the demonstration of the specific bacillus. There are many diseases which are like diphtheria in their clinical history, such as membranous croup. Then there are the cases where the disease would not have been recognized on account of the slight symptoms if the bacillus had not revealed the diagnosis, and these light cases are the very ones which spread the disease. Then our increased knowledge of this disease allows us better to understand its symptoms, and the question whether it is a local or constitutional disease is cleared up. It develops locally ; the bacilli are attached to the membrane in the pillars of the fauces, and here the toxins find their way into the body, causing the constitutional symptoms. The prognosis hinges to some extent on the demonstration of associated bacteria. Other bacteria may be associated with Loeffler bacillus in the throat ; thus the presence of the streptococcus gives an unfavorable prognosis and offers fewer chances for success in treatment. An accurate diagnosis is not only important in order to carry out the treatment, but makes it possible to take sanitary precautions. Of those who are exposed to diphtheria not a small number receive the bacillus without contracting the disease, especially in crowded districts. The organism has been found in as many as fifty per cent. of the persons exposed, whether they took the disease or not, which shows that there must be a susceptibility, which is a very important point. This susceptibility may be local, that is susceptibility exists for the local effects and not for the toxins, or the reverse may be true, the local effects may be slight and the general systemic poisoning very severe, and in some cases there is no susceptibility at all. Some cases show a thick membrane and little poisoning, and *vice versa*. The method of making a bacteriological diagnosis is a simple one. As little of the membrane as possible is taken, or some of the secretion from the posterior pillar of the fauces near the larynx. First coverslip preparations are made. If it is a case of genuine diphtheria the diagnosis can be made in about fifty per cent. of all cases without further examination. Still this is not so conclusive, as it is not quite so characteristic as the tubercle bacillus, but it is quite characteristic. For culture medium the Loeffler blood-serum mixture is used. It is usually sterilized now by exposing it to a heat just below the boiling-point for half an hour. It is easy to sterilize, since it is normally sterile, as Lister long ago showed. The mixture is opaque when rapidly sterilized and clear when done slowly. When a small piece of the membrane or some of the secretion has been smeared over the surface of the culture medium and put into the incubator at a body temperature, the culture appears in eighteen to twenty-four hours. Even if kept at the temperature of the room there will be a feeble growth. Usually the growth takes place rapidly. The difference between the growth of the true and false bacillus may be seen in the beef bouillon. In most beef, of which the culture medium is made, there is usually a little inosite or muscle sugar. This undergoes a change in color when the true bacillus of diphtheria is inoculated into it which does not occur when the false bacillus is inoculated. The question is now how to make this method of diagnosis available to all physicians. In New York City this problem has been beautifully solved, much to the admiration of the whole scientific world. Formerly many cases of ordinary angina or sore throat were called diphtheria, and much glory was reaped by the physician who cured the case. Now the bacteriological diagnosis shows that only about one in four is true diphtheria, and this not only separates the cases and makes a certain diagnosis, but it saves those other three cases from exposure to the disease, for in most instances these supposed were put at once in the diphtheria wards, and if they did not have diphtheria before, they promptly acquired it there. In carrying out the serum therapy only artifically immune animals can be used ; those naturally immuned will not do. The animals usually selected are the horse, goat, cow, and dog. The manner of procedure is to inoculate the animal selected with a minute particle, part of a pure culture of the organism. A change takes place in the blood and a new substance is found there. After each injection of the poison there is a diminution of the antitoxins at first, and then they increase, and so on until in course of time the antitoxin takes its place in the blood and a large dose of the culture will not affect the animal. This is

not exactly analogous to the tetanus injections. It takes from three to four months to immunize an animal. In simple cases where there is no association of the streptococcus, a few injections will effect a cure. Roux's experiments showed that in all cases under ordinary treatment about one-half died, whereas in the antitoxin treatment about twenty-six per cent. died. A mixture of the pure culture of the diphtheria bacillus and antitoxin in a test-tube does not destroy the bacillus but holds its action in abeyance when this mixture is injected into an animal; but if the streptococcus be added and then this mixture be injected, poisoning takes place, from which it is concluded that the streptococcus keeps the antitoxin from acting, and allows the poison to affect the victim. Roux advises against any caustic treatment of the throat, as making the cure more difficult.

Dr. James A. Steuart said that this was a great advance; that health officers had sometimes difficulty in distinguishing dangerous from ordinary cases.

Dr. I. E. Atkinson thought that such practical steps should be taken in Maryland.

Dr. John N. Mackenzie had had great success in treating diphtheria with the dioxide or peroxide of hydrogen.

Dr. John Morris thought there should be no municipal or State control of this remedy, and referred to the poor vaccine matter furnished by the State of Maryland.

Dr. I. E. Atkinson said it was largely the fault of the profession that we did not have good vaccine matter. State and municipal duties had not been carried out, and it was because the profession had not demanded them.

Dr. E. T. Duke defended the vaccine matter of Maryland, and said that as health officer of the city of Cumberland he had used it very successfully, and referred to an institution in which he had vaccinated fifty persons, and forty of them had taken.

After some discussion on the State and municipal control of the antitoxins, by Drs. G. H. Carpenter, G. J. Preston, John Morris, and W. H. Welch, the subject was closed.

Purpura Hæmorrhagica.—Dr. G. H. Carpenter then reported a case of this disease, and advocated the use of the tincture of the chloride of iron in large doses, say forty drops every two hours. He also expressed his opinion that the disease was much graver in character than was usually taught.

Electricity in Gynecology.—This was a paper by Dr. W. J. Craigen, in which he reported several cases treated by electricity, and spoke of the use of high currents and their dangers, and referred to the possibility of resuscitation after a severe electrical shock, as was suggested in New York.

Gastrostomy for Cicatricial Stenosis of the Pharynx and Œsophagus.—Two cases of this accident were reported by Dr. Randolph Winslow, and he showed how this operation had saved the life of his two cases, and gave some promise in one case of ultimate recovery.

Hysterical Pyrexia.—Dr. George J. Preston then read a paper on this subject, in which he showed that: 1. In hysterical individuals a rise of temperature may occur, due probably to disturbances of the heat-regulating centres in the central nervous system. 2. The type of this fever is either continuous or intermittent. 3. The type of fever is characterized by its great irregularity and atypical exacerbations, by the fact that the pulse and respiration frequently remain normal, or nearly so; that the temperature is often different on the two sides of the body; by the temperature not yielding readily to antipyretic measures; and by the unaltered urine and by the unchanged nutrition. 4. Hysteria often complicates existing fevers, changing their types. 5. The hysterical manifestations would be more frequently noted if the temperature were taken in all cases.

Dr. William H. Welch thought that the question of fever from central nervous origin was an important one from many points. It most likely comes from diminution of heat loss and there is no evidence of increased production. In some cases there are remarkable irregularities in heat distribution. It may be high in the vagina and normal in the axilla, and *vice versa*. By taking the surface temperature great differences may be found.

Dr. G. J. Preston had noticed many of the points above alluded to. There may be the greatest differences between the temperature of the two sides of the body. The fever may be out of all proportion to the organic lesions and may be caused by hysteria.

Chills as a Cause of Error in Diagnosis.—This was the subject of some remarks by Dr. William Osler. Chills differ very much in their etiology, but they may be divided into two main groups: 1. Those from sudden shock to the nervous system; and 2, those from absorption of the toxic material formed by organisms. In so-called nervous chill fever is absent. In the second group there is always fever. The first group need not detain us. The nervous chill is that met with in gallstone colic or in the passage of a catheter. This initial chill is without fever, but subsequently, of course, there may be chills with fever due to infection. The disease most often associated with chills is malarial fever, and here the chill is of a characteristic kind, so that the name "chills and fever" is synonymous with malaria. The two great diagnostic points in malaria are the invariable association of the plasmodium of Laveran and the invariable curative effects of quinine. These are the two special features of the malarial chill. It may be said that within forty-eight hours the chill will cease in genuine malaria if quinine be used. On the other hand, the paroxysms continue, and under its use malaria may be excluded, except in a few cases of the autumnal fevers, malarial fevers which may resist quinine for a few days, but these have not the same character of ordinary intermittents. He had not met a single instance of genuine malarial fever which quinine had not stopped.

Chills cause errors in diagnosis in various affections. In tuberculosis the error may be made early or late in the disease, for it is at the two extremes of pulmonary tuberculosis that we have chills. These are a special feature of the early stages of tuberculosis. He has had many cases of early phthisis brought to him as malarial fever. Errors occur frequently in regions where paludism is common. Then there is the large group of septic processes with fever, such as abscess of the liver, which is a common cause of chills and fever in this latitude. There are few very cases of abscess of the liver which are not at first regarded as malarial fever, and thus much valuable time is lost in the treatment. Malignant endocarditis is another disease which is ushered in by chills and which is often treated for malaria. A not frequent source of error is the chill following and associated with pleurisy of a tuberculous form and from empyema following the infectious diseases, as scarlet fever, etc., and following the formation of pus. The chills in typhoid fever are of the greatest importance, and have attracted attention for years. They occur in two or three per cent. of all cases. Very often the chill is due to the doctor's giving powerful antipyretics. He had seen cases in which chills and fever had followed a large dose of antifebrin. In certain affections of the urinary passages, and more especially in pyelitis, chills occur which are often obscure. In chronic obstruction of the common duct by gallstones there is the condition called by Charcot hepatic intermittent fever due to catarrhal cholangitis. In new growths of various kinds, as in cancer of the stomach, in Hodgkin's disease, and lastly in syphilis, errors in the fever may be made. The important points in the diagnosis of chills are the use of quinine and the examination of the blood

Dr. John Neff reported a case of fever in the course of typhoid fever in which there was a kidney complication with albumin and casts. The use of nitro-glycerine caused improvement.

Dr. Harry Friedenwald referred to a case of otorrhœa which had high fever, and which turned out to be due to a thrombosis of the lateral sinuses.

Dr. John Morris made some interesting references to the fevers of former days and the manner of treatment.

Dr. G. H. Carpenter spoke of having seen cases of tuberculosis with fever which he thought was malarial because it occurred in malarial districts. He also said he had seen a certain number of cases of fever in the course of typhoid fever which he called typho-malarial fever.

Dr. I. E. Atkinson referred to some obscure cases with fever, and he said that milk fever was a thing of the past as we know it now, and it was not due to the condition of the milk or the breasts. Septic fever occurred in the course of typhoid fever.

Dr. J. J. Wilson spoke of a case of typhoid fever in his practice in which there were several chills, and finally an abscess of the parotid gland developed.

Dr. William Osler was glad to hear Dr. Carpenter's remarks about typho-malarial fever. Many physicians treat ordinary cases of typhoid fever as malarial from beginning to end. There is no such thing as typho-malarial fever. The two diseases may exist concurrently. Quinine will cure malarial fever, but it will not influence typhoid fever at all. Cases of so-called typho-malarial fever are typhoid, and should be treated as such. Too many lives have been lost by neglect of this caution. In nearly four hundred cases of typhoid fever which had been now treated at the Johns Hopkins Hospital, in no case had malaria co-existed.

Second Day—Thursday, November 22d.

Treatment of Retro-Displacements of the Uterus.—This was the subject of a paper by Dr. Thomas A. Ashby, in which he reported several cases, with the results of his treatment. He considered the subject under four heads: The congenital; the acquired forms without adhesions; the acquired varieties associated with inflammatory conditions of the tubes and ovaries; and those cases in which the tubes and ovaries are not involved to any extent, but where the uterus is firmly attached to the pelvic peritoneum by firm bands of adhesions.

Dr. W. J. Craigen asked if he had ever had trouble with a hemorrhage after breaking up adhesions. It is not good to leave the uterus with a partially diseased stump after removal of the tubes and ovaries.

Dr. E. M. Schaeffer was glad to hear him speak of massage and also the use and abuse of the corset.

Dr. Ashby had never had any trouble with hemorrhage after the operation if the blood-vessels are looked for and tied. He does not believe in removing the uterus unless it is diseased; then tie off the stump and disinfect it, and do not remove more tissue than is absolutely necessary. This is a principle of surgery which should be followed in gynecology. Massage should always be tried first. He had seen return of the uterus to its normal position by manipulation. He believes the corset is a cause of trouble, but can Dr. Schaeffer tell us how to avoid it?

Wandering Kidney, with Report of a Case of Nephrorrhaphy.—This was the subject of a paper by Dr. R. W. Johnson, in which he spoke of the importance of a correct diagnosis and the ease of making it, and the causes. He related a case which had passed through the gynecologist's hands and had lost both ovaries without feeling better. He found a wandering kidney, which he fastened in place, and the case recovered.

Dr. Ohr referred to cases in his practice, and spoke of the difficulty of making a diagnosis of floating kidney in stout persons.

Dr. R. W. Johnson would not advise removal of the kidney unless there was some good reason for it. He is in favor of conservative surgery and referred to removals of the vermiform appendix. He did not advise operation for hernia as long as the truss will retain the hernia, and as long as the case is in a civilized region where trusses can be found and operations can be done in an emergency.

The Use of Food as Medicine.—Dr. E. M. Schaeffer read a very practical paper on this subject, showing the importance of using proper food both in health and disease and the necessity of cooking it in the right way. He showed charts illustrating the comparative values of food by bulk and nourishment, and made some strong objections to the dress of women.

Dr. E. N. Brush said that persons should be taught not only what good food is, but how to purchase it and how to cook it.

Dr. S. J. Fort said that he treated epilepsy and imbecility by giving the proper food.

Dr. William B. Canfield said that while it was eminently proper to insist on nourishing food, many persons preferred to eat what they liked rather than what was good for them, and in making a diet list palatability should be considered. Many a person sick or well preferred a savory and tempting dish, even if not so nourishing or digestible, and often the palatability made it more digestible in spite of chemistry and physiology to the contrary. The diet of rice, as pointed out by Dr. Schaeffer, may be very nourishing, but it was also constipating and not to be borne by many. He noticed that little reference was made to the use of sugar in food. He thought that the craving of children and some adults for candy was a natural one, and he did not think good candy in moderate amount was injurious.

Dr. G. H. Carpenter said he knew more about cattle-raising than he did about bringing up a healthy race, and the former was much easier. He agreed with Dr. Canfield in what he said about the palatability. Natural selection in the human race is hard to carry out in practice. It is important to gratify the appetite when no actual harm is done.

Dr. T. A. Ashby said that disease in women was divided into two classes, that in the married and that in the unmarried. In the sterile woman the disease is generally from some defect formed in childhood. Then hygienic measures are important. About ninety per cent. of the diseases in child-bearing women are due to the child-birth. Sexual selection is ideal, and so also are the charts which Dr. Schaeffer shows.

Dr. Schaeffer said in conclusion that rice constipates because it was so thoroughly digested that there is little residue. There is no waste as in other foods. Rice properly cooked forms a very palatable dish. The Chinese recognized the value of rice when they ate rice and butter.

Treatment of Insomnia.—Dr. E. N. Brush read a paper on this subject. He deplored the multiplication of hypnotics, which had been encouraged by physicians so much of late, and spoke of natural methods as inducing sleep. He referred to baths, proper clothing, and attention to general hygiene.

Dr. Schaeffer agreed with Dr. Brush, and thinks that attention to food and drink will often take the place of drugs, as he had already shown in his paper.

Pseudarthritis.—Dr. S. J. Fort then presented a paper on this subject in which he related cases of hysterical joint trouble simulating rheumatism in children.

Treatment of Pulmonary Consumption in Large Cities.—Dr. William B. Canfield read a paper on this subject in which he referred to the great advances made in the pathology of that disease and the failure as yet to find a specific remedy. He said that cod-liver oil and tonics were still relied on in most large cities. Out-door life, equable climate, good food, comfortable clothing,

slight occupation in some cases do more than drugs. With our present light the proper treatment of consumption in large cities, especially the incipient cases, is by small hospitals where each case can be individually studied.

"Spring Catarrh of the Conjunctiva" was the subject of a paper by Dr. Harry Friedenwald. "Dirty Air in Public Places" was a paper by Dr. E. M. Schaeffer.

Papers by Dr. George Thomas on "Illumination of the Accessory Cavities," and by Dr. J. T. Smith on "Acute Pericarditis," were read by title. The profession of Cumberland and vicinity were very cordial to the visiting physicians.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE BRADSHAW LECTURE—JAMES SYME AND HIS AUTHORITY IN SURGERY—THE MEDICAL COUNCIL AND THE OBSTETRICAL SOCIETY'S SHAM DIPLOMAS—DEATHS OF DR. WITHERSMOORE, DR. JOHN CHAPMAN, AND DR. BISSETT HAWKINS.

LONDON, December 15, 1894.

THE Bradshaw lecture was delivered on Wednesday, (12th), before the College of Surgeons, by Mr. Oliver Pemberton, of Birmingham, who is to be congratulated on stepping out of the usual run of subjects. He devoted the lecture to James Syme, his influence and authority on the art and science of surgery. Syme was professor at Edinburgh from 1833 to 1859, and during the whole time he had a most remarkable influence—perhaps no one has exercised a more emphatic authority, certainly no one has excelled him in the value of his suggestions for saving lives and limbs in the practice of surgery. Mr. Pemberton naturally drew attention to the fact that in his earlier years Syme had not the advantage of anæsthetics. The greater difficulties of surgery in the early period ought not, therefore, to be forgotten. In 1828, when he had no hospital appointment, Syme performed excision of the elbow-joint for the first time in Great Britain, and to him is due the honor of establishing that operation. To him is also due the honor of introducing into this country and perfecting tibio-tarsal amputation—a procedure which, however, had been previously tried on the continent. Still previous operations were not to be compared to Syme's, for modern success is due to his ingenious improvement which secures the pad of the heel as the covering for the joint. This procedure, the lecturer said, was adopted by Syme in 1842. The next illustration of surgical genius offered was the treatment of urethral strictures; as to which Syme taught that, 1, no stricture is truly impermeable; 2, that all which cannot be relieved by dilatation admit effectual relief only by free division of the contracted part of the canal; 3, this can only be attained with certainty and safety by external division. Thus Syme was the first to practice external urethrotomy, and his skill and success were most remarkable, for he only lost two cases out of one hundred and eight. The lecturer then referred to Syme's success in dealing with aneurisms, and showed that this success depended on his departure from the Hunterian method, which had previously ruled. In this connection he remarked that he had "a happy touch in dealing with arteries," for he tied the femoral twenty-five times with but one failure, from suppuration of the sac caused by prolonged pressure and the ill health of the patient. Syme also excised the greater part of the inferior maxilla in 1827 for an enormous growth involving the bone, and the case is an historical success. The lecturer concluded by an appeal to the members of our calling, wherever English surgery is known, to endorse the view that in contemplating Syme's professional life we see an authority in the practice of our art approached by few, surpassed by none.

After the lecture the audience had an opportunity of examining the specimen of the successful operation on the jaw mentioned above.

The Medical Council has perhaps never done anything more satisfactory to the general practitioner than in passing the resolution pronouncing it "infamous in a professional respect" for registered practitioners to issue documents which are "colorable imitations" of diplomas entitling the holders to registration. The council followed this up by declaring the certificates issued by the Obstetrical Society to come within the purview of their resolution and directing this opinion to be communicated to the Society. Much satisfaction is freely expressed at this course. Although here and there some excuse has been offered for the Society in times past, it has long been felt by most people that the unauthorized assumption of the Society must be injurious, and not a few have from the first held that severe condemnation was called for. The Society has no status whatever as an examining body, and the issue of certificates to midwives was certain to lead to the certificated practising on such "diplomas," which have no more value than the testimonials of any registered practitioners. Now that the Medical Council has put its foot down, the Society must amend its ways, and the more quickly and gracefully it complies with the requirements made, the more likely are its past offences to be condoned. Any hesitation must be treated with the same justice as is being so properly meted out to other delinquents.

The death roll of the profession is continually being added to. Among notable men recently deceased is Dr. Withers Moore, who was president of the British medical meeting at Brighton in 1886, when, with many others, I had the opportunity of witnessing the energy, impartiality, and urbanity with which he discharged his duties. He retired some time since and died rather suddenly from angina pectoris on the 5th inst. in his seventy-first year.

Dr. John Chapman died at Paris aged seventy-two. He was a man of distinguished physique and great intellectual endowments. Your readers will remember the ability with which he deduced his views of vaso-motor therapeutics and maintained the possibility of greatly influencing this system by the application of warmth or cold to different parts of the spine. The use of cold proved the more important agent, and Dr. Chapman was known to not a few as the advocate of ice-bags to the spine in numerous conditions. He was, however, engaged in other work as well as the practice he carried on in London and subsequently in Paris. He was for many years the proprietor and editor of the *Westminster Review*, one of our most able quarterlies, which not long since became a monthly.

Dr. Francis Bissett Hawkins, who died on the 7th at Bournemouth, seems to belong to the long past, for he had reached the great age of ninety-eight. He was said to be the oldest living Oxford graduate, and was Senior Fellow of the College of Physicians, of which he had been Senior Censor, and held other offices. He had also had government offices in his day, such as inspectorships and commissionerships of prisons, in lunacy, etc. He was a Justice of the Peace and had retired many years. He wrote in the "Encyclopædia of Practical Medicine" issued in 1835.

The Pittsburg Academy of Medicine is a flourishing society. It has been in existence five years, and during that time it has established a nurses' directory, a pathological laboratory, and formed the nucleus of a library. Recently it has undertaken to make diphtheria antitoxin and furnish it under direction of the city government. It is hoped that it will, before long, be housed in a properly equipped building of its own.

THE DIAGNOSIS AND ANTITOXIC TREATMENT OF DIPHTHERIA.

(Special Report to the MEDICAL RECORD.)

DR. GERMAN SIMS WOODHEAD, the distinguished Director of the Research Laboratories of the Royal College of Physicians and Surgeons, London, delivered a lecture on this subject recently at the Examination Hall. This lecture, which has been looked forward to as an almost authoritative exposition of the present aspect of the subject, was listened to with rapt attention, and will go far to promote cautious scientific views.

Dr. Woodhead opened his lecture by brief remarks on the increase of diphtheria in London, where last year the deaths were 3,195 as against 1,962 the year previous. Having added some statistics of the incidence of the disease at different ages, and a brief historical summary of the investigations of Klebs, Loeffler, and others, the lecturer went on to say that these observers agreed that the micro-organism found in the lesions had perfectly definite characters. In the false membrane it usually occurs as small rods about 3 to 6 μ in length, rather shorter than the tubercle bacillus, but from one and one and a half to twice as thick. It is straight, or very slightly curved, rounded at the ends, and these, somewhat enlarged, are more deeply stained than the central portion. It occurs singly or in groups, forming, when in sufficient numbers, a kind of interlacing reticulum or irregular masses of considerable size. In a case of true diphtheria these bacilli are almost invariably found on the surface of the false membrane, while in other cases they are situated somewhat more deeply, but are seldom, if ever, found in the mucosa, that is, the true mucous membrane, from which they are separated, according to Loeffler, Roux, Yersin, and Ruffer, by a layer of fibrous lymph in which are found numerous leucocytes.

Loeffler first pointed out that the bacillus did not make its way into the tissues and fluids of the body, but that it appeared to form most powerful toxic substances, apparently from the fibrinous effusion, and that these toxic products, rapidly taken into the circulation, set up the grave constitutional disturbance seen in this disease. These toxic substances were afterward studied more carefully by Roux and Yersin, who came to the conclusion that they were most powerful poisonous substances, probably of the nature of enzymes, which in exceedingly minute doses were capable of setting up profound toxic processes. Sidney Martin then worked out the subject carefully and thoroughly, agreed generally with previous observers, and obtained still more accurate results, for he was able to separate from the spleen of diphtheritic patients two substances, one apparently of the nature of an organic acid, and the other of a poisonous albumose, while from the false membranes he obtained a much more highly toxic substance, corresponding to Roux and Yersin's enzyme. He concluded that this enzyme, absorbed into the body, acts upon the proteids of the spleen and gives rise to the less poisonous, but still very active, organic acid and tox-albumoses All these substances appear to act specially on the peripheral nerves and upon muscles, setting up in these structures what he describes as segmental neuritis in the one and fatty degeneration in the other. The methods of microscopic diagnosis were then described, and Dr. Woodhead said that the Metropolitan Asylums Board had decided that a bacteriological examination of the fauces of patients suffering from diphtheria, both when they come into and are discharged from their hospitals, is advisable, especially as the preliminary steps of the process are readily carried out with very little expenditure of time on the physician's part, and with no discomfort and absolutely no danger to the patient.

He then stated the arrangements made, which are that from his laboratory will be sent out to the various hospitals under the management of the Board, as required, small cases containing, 1, a test-tube (plugged with sterilized cotton wadding) in which is a quantity of suitable solidified nutrient medium carefully sterilized; 2, a second tube, also plugged with cotton wadding, in which is held a small, soft steel rod, roughened at the end, around which is fastened a pledget of cotton wadding, the whole being carefully sterilized by dry heat. When a case of diphtheria is to be examined all that is necessary to be done is to take these tubes from the box, take out the wire with the pledget of cotton wool, and press it gently but firmly against the membrane of the throat or at the place from which the membrane has disappeared. The serum tube is then opened and the pledget is drawn carefully once or twice from bottom to top of the inclined serum surface. The cotton-wadding plug is returned, the wire with the pledget is replaced in the empty tube, and the box is packed up and sent at once for investigation to the laboratories. In those cases in which fragments of the membrane can be easily detached it is advisable, with a platinum spatula previously heated and allowed to cool, to remove a fragment and to place this in the tube along with the iron wire. Such a fragment may be used in case the first inoculation fails to give the necessary results. The serum tube is placed in the incubator, and is examined at intervals until growths make their appearance, eight to twenty hours at the latest, so that the case, even when inoculations are to be made, can be reported upon within twenty-four hours of the receipt of the material.

Dr. Woodhead next passed on to the consideration of the method of preparing toxins from the diphtheria bacillus, the process of immunization of the horse, and the method of testing the immunized serum, after which he gave the results of the serum treatment obtained in Paris, Berlin, and Budapest. These results were most striking, and the introduction of the treatment had been followed by diminutions in case-mortality in one instance from 51.7 to 24.5 per cent.; in others from 34.7 to 23.6; from 25 to 20; from 46.5 to 33.3; and from 53.8 to 33.1 per cent. The necessity for carefully carrying on and improving, if possible, the method or treatment by serum is proved, Dr. Woodhead held as follows: First. By the results obtained from clinical examination. Second. From the startling results obtained by experiments on small rodents, which can easily be protected against enormous doses of most active diphtheria toxin. Third. From the remarkable property possessed by this antitoxic serum of neutralizing the diphtheria toxins, even when the process is carried out in an ordinary test-tube. Fourth. From the fact that in diphtheria the disease is essentially the result of the manufacture of poison practically outside the body, so that if we can attack the disease at its source, and can at the same time neutralize the poisons that are diffused into the body, we have the control of the disease; and as the disease runs such a rapid course it is possible to ascertain whether the case is improving or going backward almost immediately, or within the course of thirty-six hours. When the disease is once got under we have little or no fear of any return. Fifth. It is not even a process of vaccination, though it is quite possible, from what has been seen in experiments on animals, that a temporary protection may be obtained which will carry the child over the period of danger in an infected house or district. The antitoxic serum is a direct therapeutic agent, only to be used in patients actually suffering from the disease. Sixth. Cautious observers, both among pathologists and physicians who have had an opportunity of observing a number of cases treated, have acknowledged that they have been surprised at the results obtained, and Virchow, who almost from the first deprecated the extravagant claims that were put forward for Koch's tuberculin, has stated that, in view of the remarkable results obtained in carefully observed cases of diphtheria, it is

the duty of every physician to employ the antitoxin serum remedy, in spite of the fact that a certain number of attendant drawbacks have been described.

Dr. Woodhead declared that a good deal of nonsense has been written about the danger of injecting organic fluids into the body, especially organic fluids taken from animals suffering from disease—such as glanders and tuberculosis. The obvious answer to such objections is, that the serum is never taken from an animal so diseased. If mallein—that is, the products of the glanders bacillus from which living bacilli have been absolutely removed—is injected into the subcutaneous tissues of a healthy horse there is as little disturbance, either local or general, as if a similar quantity of neutral salt solution had been injected. But if the animal has glanders when this material is injected, we have a local manifestation at once; a swelling at the point of injection, the temperature of the animal rises, and this so regularly that anyone accustomed to the use of mallein as a diagnostic agent can determine within twelve hours whether the horse is suffering from glanders or not. By the use of tuberculin in a similar fashion the freedom of the animal from tuberculosis can be determined, so that the horse may very readily be proved to be in good health, as far as these two diseases (the only two dangerous to man about which there is much difficulty of diagnosis) are concerned. It has also been asserted that the horse is suffering from diphtheria, and that only the poison which is accumulated in the blood is injected into the human patient. Against this may be placed the fact that the toxin will certainly not neutralize its own action, and if we were dealing simply with toxin we should have not an antidotal, but, on the contrary, an accumulative effect. Many of those present, he said, have seen cases of diphtheria, at first apparently mild, gradually develop the most distressing symptoms. Nothing was more pitiable or painful than to see the distress of the little sufferers as the disease has become more fully developed, and one has felt one's utter helplessness to relieve more than temporarily the dreadful suffering one has had to witness. "I for one," said Dr. Woodhead—"and I am sure that in this my feelings are shared not only by medical men but also by those who have had to watch and wait while such scenes were going on—feel that any remedy that promises results even far less favorable than those claimed for this method of treatment, should be placed at the disposal of those who have to do battle with this terrible disease. We must improve the sanitary conditions and the general surroundings of those who are most liable to the disease, in order to prevent the disease or keep it at as low a limit as possible, but we have also a duty to perform to those who are actually smitten down." In conclusion, Dr. Woodhead drew attention to the munificence of the Goldsmiths' Company, who have placed at the disposal of the Royal College of Physicians and Surgeons the sum of $1,000, to be devoted, in the first instance, to the defraying of the cost of investigations directed to the elucidation of some of these obscure points, and, in the second place, to the preparation of antitoxic serum for the treatment of the poor of East London. Also to the public spirit of the Metropolitan Asylums Board, who, in the interests of their patients, have been the pioneers among the public bodies in this country in instituting bacteriological examinations of their cases of diphtheria with a view to clearing up the diagnosis in some, at any rate, of the dubious cases. Their efforts, he said, are appreciated by the Laboratories Committee, who will give all the help that is in their power to make these investigations useful as regards their patients and helpful to those on whose shoulders rests the serious responsibility of diagnosis.

A Fresh Drink.—Figg—How well you're looking! Fogg—Yes, I've been drinking well water all summer.

TESTIMONIAL TO SIR JOSEPH LISTER.

To the Editor of the Medical Record.

Sir: Sir Joseph Lister, having recently retired from active hospital and teaching work, the occasion has been thought appropriate for presenting him with a testimonial of the esteem in which he is held by his former colleagues and pupils, and committees have therefore been formed in Glasgow, Edinburgh, and London for the purpose of raising the necessary funds. It is proposed that the testimonial shall take the form of a portrait. Subscriptions have been limited to two guineas, and it is hoped that sufficient funds will be collected to permit of some memento of the occasion being presented to each subscriber of that amount.

As there are probably many surgeons in the United States who may wish to join in the movement, but whose names and exact addresses it has been difficult to ascertain, I should be glad if you would permit me to state that subscriptions may be sent to me at 29 Weymouth Street, Portland Place, London, W., England, or to one or other of the following gentlemen who have kindly consented to act as treasurers, viz.: Dr. James Finlayson, 4 Woodside Place, Glasgow, Scotland; Professor Chiene, 26 Charlotte Square, Edinburgh, Scotland; Professor William Rose, 17 Harley Street, London, W., England; Dr. Malloch, 124 James Street, South Hamilton, Ontario; or J. Stewart, M.B., 37 South Street, Halifax, Nova Scotia.

I have the honor to remain, Sir,

Yours faithfully,

J. Frederick W. Silk,
Honorary Secretary.

P. S.—Two guineas are about $10.23.

"VAGINAL HYSTERECTOMY BY ENUCLEATION."

To the Editor of the Medical Record.

Sir: In your issue of December 1st, 1894, under the above heading, appears an interesting record of a case in which the removal of the uterus through the vagina was effected without either clamp or ligature. At the end of his article Dr. Goffe remarks: "The operation was done at the New York Skin and Cancer Hospital, October 12, 1894, and I believe it is the first time the operation has ever been done in New York." Having seen Dr. Pratt, of Chicago, perform several vaginal hysterectomies without the use of the clamp or ligature in 1893, I determined to follow his example, as it appeared to me the operation was based upon sound principles. My first vaginal hysterectomy was done on June 27th; my second on September 19th. In neither of the cases was the clamp or ligature required, the patients making remarkably rapid recoveries.

Very truly yours,

W. T. Helmuth, Jr., M.D.

FOOT-BALL AS IT SHOULD BE.

To the Editor of the Medical Record.

Sir: Your editorial in the Medical Record of December 1, 1894, on the "Brutality of Foot-ball," was very timely. But you well say that "there is no game that equals it in many ways when played as a manly sport and not for gate receipts." It is the gate receipts which inspire the short-haired to "slug" for the belt, and it may be that the long-haired have thoughts of them when they indulge in "hacking."

The occasional injury received at foot-ball is now the cause of war, but if the financial managers of teams do not curb their apparent immense extravagance, foot-ball advocates will be put on the defensive. For, according to a newspaper report, the expenses for four games lately played by a Northern team were over $20,000!

Last season's manner of playing was a renaissance of "Tom Brown's School Days," which resembled the Roman *harpastum*, to seize, etc. But this was not the foot-ball game as played by the refined Greeks.

The rough Rugby game of seizing and carrying the ball, charging, and "tackling," which game we play, is not the Harrow and Winchester game, wherein kicking alone is allowed.

James the First forbade the heir apparent playing the game of his day, saying that it was "meeter for laming than making able the users thereof."

As I have lately witnessed several games, and have been in close contact with foot-ball men both in the class-room, and on the field, and at the table, I will give a few impressions of them, and of the game.

The team of the University of Virginia, the champions of the South, played nine games, and it played such teams as the Princeton, and the University of Pennsylvania. Only two or three of them received such injuries as to keep them from the class-room a single day. One of them, a man about twenty-seven years of age, had a doubtful fracture of a clavicle, and the other skinned knees.

As the tragic actor knows how to make the fall when struck or shot down, so properly trained foot-ball men know how to fall. The candidate for the team has to be physically examined by a competent physician.

The game should be played on a well-turfed field, and men over twenty-five years of age should not play the game of 1894. Injuries to them may be serious. When one of delicate sensibility sees for the first time a game of foot-ball, he thinks that the police and the ambulance corps should be called in, but he will be early seen at the next game, and the next.

The diet, the abstinence from alcohol and tobacco, and the general training of a foot-ball man are of course most conducive to health of body and mind, and as a consequence his class standing is near the top; and according to the regulations of athletics by the Faculty Committee of the University of Virginia, "any member of an athletic team who is reported for neglect of his studies or non-attendance on lectures, may be required by the Faculty to sever his connection with such team."

The cold bath after an exhaustive game is of doubtful propriety. Emergent action, quick memory—for more than sixty rules regulated the game as far back as sixteen years ago—and herculean body, are most eminently promoted by foot-ball.

Thomas R. Evans, M.D.

Nuttallburg, W. Va.

THE ASSOCIATION OF MEDICAL OFFICERS OF THE NATIONAL GUARD AND NAVAL MILITIA OF THE STATE OF NEW YORK.

To the Editor of the Medical Record.

Sir: In your issue of December 1, 1894, page 696, in an item entitled "New York State Association of Military Surgeons," you give a list of officers elected. This, I believe, was the Association of Railway Surgeons. The military association is known as "The Association of Medical Officers of the National Guard and Naval Militia of the State of New York."

The present officers of the Association are as follows: *President*, Dr. Joseph D. Bryant, of New York City; *Vice-Presidents*, Dr. D. M. Stimson, of New York City; Dr. William H. Spencer, of Brooklyn; Dr. Herman Bendell, of Albany; Dr. A. H. Briggs, of Buffalo; *Treasurer*, Dr. Nelson H. Henry, of New York City; *Secretary*, Dr. Daniel S. Burr, of Binghamton. Officers ex-officio members of the Executive Committee.

Additional members of the Executive Committee: Dr. Robert V. McKein, of New York City; Dr. George R. Fowler, of Brooklyn; Dr. Lewis Balch, of Albany; Dr. Charles N. Cox, of Buffalo; Dr. John Vander Poel.

Respectfully,

Nelson H. Henry.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 5, 1895.

	Cases.	Deaths.
Tuberculosis	54	77
Typhoid fever	8	6
Scarlet fever	111	11
Cerebro-spinal meningitis	2	4
Measles	64	11
Diphtheria	218	46
Small-pox	5	0

The Medical Staff of the West Side German Dispensary has organized a clinical society under the name of the "Society for Medical Progress of the West Side German Dispensary." The officers for the first year are: *President*, Augustin H. Goelet; *Vice-Presidents*, Lewis Morris and V. Fuentes; *Secretary*, Aristides Agramonte; *Treasurer*, H. C. Hazen.

The Award of the Saint-Paul Prize.—About fifteen years ago the sum of 25,000 francs was given to the Paris Academy of Medicine by M. and Mme. Victor Saint-Paul as a prize to be awarded by the Academy to anyone who shall have discovered a remedy "recognized as efficacious and sovereign against diphtheria." There are no other conditions than this—the contestants for the prize may be of any nationality and of any profession. The prize was established in memory of a son of the donors who died of diphtheria in Turin while on his way home from a journey in the East. Since its foundation the Academy has been inundated with treatises, prescriptions, letters, and even telegrams, sent from all parts of the world by enthusiasts who believed that they had at last discovered the sovereign remedy. The question now is, will the Academy award the prize, and if so, will it give the same to Behring, to Roux, or to whom?

The Influence of Albinism upon the Eye.—Dr. George M. Gould desires information as to the condition of the eyes of albinos, and requests all who have had albinotic patients to send answers to a set of questions which he has drawn up for this purpose. The blanks will be gladly sent on application to Dr. Gould, 119 South Seventeenth Street, Philadelphia, Pa.

Two Operations for One Appendicitis.—Dr. Olaf Page, of Valparaiso, Chili, reports a case in which he operated for an acute appendicitis. The case progressed favorably for a week, and then the symptoms of obstruction returned and death seemed imminent. The wound being reopened, it was found that the trouble arose from constricting bands on the left side of the abdominal cavity. The original wound was now closed, and a median laparotomy performed through which the bands were reached and divided. After this there was no further trouble.

Verdict Against a Physician.—A verdict of $12,000 was awarded by a jury a few weeks ago against Dr. L. H. Willard, a prominent homœopathic physician of Pittsburg, in a malpractice suit. The plaintiff, a charity patient, was treated by Dr. Willard at the Homœopathic Hospital of Pittsburg for a fracture of the fibula. He left the hospital against the advice of Dr. Willard, and was subsequently treated by a physician in Somerset County, who testified that both bones of the leg were broken. A number of well-known physicians testified that the injury was properly treated by Dr. Willard. The case had been tried twice before. The first time the jury awarded the plaintiff $5,000 damages; in the second trial the jury disagreed.

THE TREATMENT OF INOPERABLE MALIGNANT TUMORS WITH THE TOXINS OF ERYSIPELAS AND BACILLUS PRODIGIOSUS.[1]

BY WILLIAM B. COLEY, M.D.,

ATTENDING SURGEON TO THE NEW YORK CANCER HOSPITAL; ASSISTANT SURGEON TO THE HOSPITAL FOR RUPTURED AND CRIPPLED.

I AM conscious that the treatment of inoperable tumors is a very trite subject, yet in consideration of the fact that practically no advance has been made in this field since the disease was first known, I am sure I need offer no apology if I can show that there has been even a single step forward. No one can blame the profession for sound conservatism, or even scepticism, in regard to anything that is claimed to cure inoperable malignant tumors. Past experience fully justifies its attitude, and I believe it should not accept a single statement until it has stood the rigid tests of scientific demonstration. By these tests alone I desire you to judge the cases I have already reported, as well as those I have the pleasure of presenting to-night. My results in thirty-five cases of inoperable tumors treated with the toxins during the past three years, were reported in detail at the last meeting of the American Surgical Association,[2] at Washington, May 31, 1894, and will be only briefly referred to here.

Four very remarkable successes since then, and the additional experience gained from the observation of twenty-four new cases, are, I think, sufficient reasons for bringing this subject again to your attention.

Up to last May my cases were treated with the filtered toxins, prepared by growing the erysipelas streptococci in bouillon three weeks, then filtering through porcelain, and preserving by adding thymol. The toxins of bacillus prodigiosus were prepared in the same way, and the two were mixed at the time of using. In some of the cases the two germs were grown together in the same flasks, and then filtered. This method of preparation failed to utilize whatever of value exists in the bodies of the germs themselves, and I decided to try preparing the toxins by subjecting the cultures to the lowest temperature that would suffice to destroy the germs. This I found by experiment to be about 58° C. This preparation has been used exclusively in the series of twenty-four cases which I report to-night, and it is, I think, much more efficacious than the filtered toxins.

The following is a brief history of the more important cases treated since June 1, 1894, and not yet reported:

CASE I.—Female, twenty years of age. Recurrent spindle-celled sarcoma of palm of hand; six operations. This case appears in the tables of my previous paper (*loc. cit.*) as Case VI., and is merely mentioned as having shown marked improvement, and as being still "under treatment." The subsequent history makes the case worthy of a fuller report.

The first operation was performed in the fall of 1888. The tumor did not recur until the summer of 1891. A second operation was performed and recurrence again followed: the third, fourth, and fifth operations were performed, recurrence each time occurring after shorter intervals.

The fifth operation was performed in January, 1893, by Dr. Samuel Lloyd, of New York, and recurrence followed within three weeks. I saw the patient, in consultation with Dr. Lloyd, in February, 1893, and at that time a tumor, the size of half a hen's egg, was seen in the palm of the right hand at the site of the old cicatrices. It was a typical sarcoma clinically, and the diagnosis had been repeatedly confirmed by microscopical examination. Amputation of the forearm had been very strongly urged, but the patient refused consent to such operation. The axillary glands were slightly enlarged, her general condition was only fair. Injections with the mixed toxins were begun under my direction, and often by myself personally, and the treatment was continued by Dr. Lloyd, with longer or shorter intervals, during the whole spring. The tumor decreased some in size and failed to grow when the injections were stopped for a short time. She had little treatment during the summer, and in October, 1893, the axillary glands were very much enlarged. The tumor in the hand was also beginning to increase in size. Dr. Lloyd operated upon the axilla and removed several glands, some of which were as large as large olives, and typically sarcomatous. The tumor of the hand was then treated with the injections of the mixed toxins.

The patient was unable to remain in a hospital, and the injections were given at Dr. Lloyd's office. This made it impossible to push the injections to the desired limit, and made the treatment otherwise unsatisfactory. Whenever the injections were given regularly and in fairly large doses the tumor remained in control, and furthermore decreased in size.

In June, 1894, she was admitted to my service at the New York Cancer Hospital, and the injections were pushed to their limit for about three weeks. The tumor softened and also decreased some in size. As the patient's general condition had been running down for several months, I thought it wise to give ether and scrape out the more or less necrotic sarcomatous tissue. It was found to extend very deeply, entirely surrounding the palmar tendons of the middle, ring, and little fingers, and infiltrating between the metacarpal bones so as almost to appear on the dorsal side. It was removed as well as possible with a Volkmann spoon and scissors, and the extensive wound allowed to heal by granulation; no further injections were given. She quickly began to improve in health, and has now regained her normal weight and strength. She has gained twenty pounds since July. No trace of any trouble can be detected either in the hand or axilla. This case is important, as it shows that a rapidly growing sarcoma was held in check one year and a half by the toxins, even when given under unfavorable conditions, and also that the malignancy of the disease was probably destroyed.[1]

CASE II.—This case I owe to the courtesy of Dr. George F. Shrady, who kindly asked me to begin the treatment at St. Francis Hospital. Bernard M——, aged twenty-three, German, printer by occupation. His family history is good, and up to one year ago he had enjoyed perfect health. Ten years ago he fell from a fourth-story window, but was supposed to have suffered

[1] Read at the General Meeting of the Academy of Medicine, November 15, 1894.

[2] American Journal of the Medical Sciences, July, 1894.

[1] The case remains in perfect health January 1, 1895, nearly six months since cessation of treatment.

no permanent injury. Three years ago he fell in the streets, striking upon his back. He, however, noticed no trouble from either of these injuries, until one year ago a tumor appeared in his back, in the region of the right buttock. There was little pain, and his attention was first called to it by the fact that he was unable to button his trousers. The tumor was hard, apparently rising from the ilium, and gradually extended until it had involved nearly the entire right half of the ilium. In February, 1894, it had reached the size of a child's head, and extended from the middle of the sacrum behind nearly to the edge of the rectus muscle in front, filling up a large portion of the right iliac fossa. The tumor was firm in consistence, the skin over it normal, and not adherent. The right inguinal glands were very much enlarged. The patient was considerably emaciated, and was losing flesh and strength rapidly. He was shown at the New York Academy of Medicine by Dr. Kammerer, in February, 1894, before the Surgical Section, and the question as to the advisability of subjecting him to the treatment with erysipelas and prodigiosus toxins was discussed. The weight of opinion was that the tumor was too large and the case too far advanced to offer even a hope of success. It was thought best, however, to try the injections for a brief time, and the treatment was begun at St. Francis Hospital in March 1894. Injections were continued at intervals of twenty-four to forty-eight hours for a period of one month. The tumor very quickly began to break down, and fluctuation appeared over a large area. Free incision and irrigation were employed, and the tumor continued to break down and slough out in large masses for a number of weeks after the injections were stopped. The patient was considerably depressed both by the treatment and by the sloughing process, and for some weeks his condition was exceedingly critical. His temperature ran very high for a month after the injections had been stopped, due to the absorption of the broken-down tissue. As the discharge began to diminish, his condition improved, and by June he was able to be up and about the ward. Since that time he has steadily improved, regaining his flesh and strength with remarkable rapidity, and on September 12, 1894, physical examination was as follows: In right lumbar region, one inch below the crest of the ilium, is a cicatrix three inches long with a small sinus at either end. Two inches below this cicatrix is another small sinus; four inches further down a third. No dead bone can be detected with a probe, and there is only a slight discharge from the sinus. The inguinal glands on the right side are slightly enlarged, but steadily diminishing in size. There remains no trace of the large tumor already described at the beginning of the treatment, and the general condition of the patient has nearly returned to normal. He now weighs (November 15th), one hundred and forty-eight pounds, a gain of twenty-nine pounds since August, and fully forty pounds since June. He has resumed his occupation as a printer.

I will say that no microscopic section was examined before treatment was begun, but the clinical history and physical examination, verified by a large number of surgeons of the Surgical Section at the Academy, left no doubt as to the diagnosis. It was an osteo-chondro sarcoma, as several hard cartilaginous masses sloughed out, examination of which showed them to be chondroma. The majority of the tumor was sarcomatous tissue.[1]

Case III. *Spindle-celled Sarcoma of Scapula with an Extensive Involvement of Chest-wall.*—Sarah C——, aged sixteen, was admitted to the New York Cancer Hospital June 20, 1894. There was no history of malignant disease in the family, and her personal history was good up to four months previous to admission. At that time she first noticed a small tumor in her back, over the left scapula. The tumor rapidly increased in size, and gradually extended, both in front and behind, until it had involved the larger portion of the left thoracic wall. It was associated with constantly increasing pain and interference with the movements of her arm. Physical examination, June 25, 1894, showed the following condition: There was a hard fixed mass involving almost the entire region of the left thorax behind, extending from the clavicle to the lowest rib, vertical measurement being thirteen inches. Horizontally it extended from the median line behind to the middle of the sternum in front, and from one inch below the clavicle seven inches downward, involving a large portion of the region of left breast. The entire tumor was firmly fixed to the chest-wall, but the overlying skin was normal in appearance, and not adherent. The left arm could not be raised to a right angle, and movements forward and backward were correspondingly limited. A portion of the tumor was removed, and microscopical examination proved it to be a spindle-celled sarcoma. In consideration of the rapidity of the growth and enormous extent involved, I did not believe even temporary arrest possible, nevertheless I decided to try the injections for two or three weeks and watch the effect. To my astonishment, improvement was immediate and very rapid. Within three weeks the arm could be raised to a vertical position, and within one month the growth in front had nearly disappeared. The injections were continued at intervals of from twenty-four to forty-eight hours, and the reactions were never severe enough to keep the patient in bed more than a few hours after the injection. The improvement continued without any interruption until the latter part of October, when no trace of the tumor could be found either in front or behind. The treatment has been discontinued since that time, and the patient is presented this evening without the slightest suspicion of the sarcoma or even any induration visible. She has regained her normal weight and her usual health and strength.

This case is to my mind the most brilliant of the entire series, and must be regarded as the crowning triumph of the toxin treatment. Here we have a tumor, the great malignancy of which was shown by the rapidity of its growth and the extensive involvement that had occurred within four months, and the diagnosis of spindle-celled sarcoma established by the microscopic examination of a skilled pathologist,[1] entirely disappearing within three and a half months from the beginning of the treatment with the mixed toxins.

There are some points of unusual interest in this case. 1. All of the injections were made in one portion of the tumor, over the lower part of the scapula, and within a radius of two inches. 2. There was no breaking down, the tumor disappearing entirely by absorption. 3. Only a single preparation of the toxins was used throughout, viz., mixed cultures of erysipelas streptococci and bacillus prodigiosus, grown together in bouillon and sterilized by subjecting them to a temperature of 58° C.

Case IV. *Probable Sarcoma of Sternum.*—The patient, aged thirty-nine, female, was first seen by me in consultation with Dr. Farquhar Ferguson, August 21, 1894. Two of her sisters had suffered from cancer, but she herself had been well up to four months before consulting me. At that time she noticed a small swelling over the upper portion of the sternum. It steadily increased in size, was but slightly painful, and seemed fixed to the sternum. Her general health had become considerably impaired and she had lost weight. Physical examination showed the upper third of the sternum occupied by a tumor three inches in diameter, symmetrical in outline, and firmly connected with the ster-

[1] Since the paper was read, a portion of the thickened ilium at site of tumor was removed, December 1, 1894, for examination, and no trace of sarcoma could be found on microscopical examination.

[1] Dr. G. F. Brooks, Pathologist to Post-Graduate Medical School and Hospital.

num itself. In consistence it was about the same as an ordinary sarcoma when the cellular structure predominates. A few enlarged glands were present along the border of the left pectoral muscle.[1] The injections were begun August 23, 1894, and severe reactions followed the administration of very small doses. The injections were repeated every other day, and at the end of the first week most of the tumor was soft and fluctuating. A small incision was made under cocaine and the broken-down material allowed to escape. The injections were continued in the portions of the tumor still hard for about four weeks longer. At the end of that time it had apparently disappeared, there only remaining two small sinuses at the points where incision had been made to permit the degenerated tumor-tissue to escape.

Her general health has much improved, and although the case is too recent to speak of it as a permanent cure, the results in my earlier cases make it not unreasonable to hope for a cure in this case.[2]

Carcinoma.—Of the cases of carcinoma I have only time to mention in detail a single case.

Mrs. W——, aged thirty-four, with a good family and previous personal history, came to the Methodist Episcopal Hospital in July, 1894, with a very rapidly growing epithelioma of the lower jaw, involving the floor of the mouth, under portion of tongue, and all of the soft tissues of the chin. There was an area the size of a silver half-dollar, the site of a typical epitheliomatous ulcer. The tumor had followed quickly an injury to the chin, and this fact in connection with the age of the patient, would have pointed to a diagnosis of sarcoma, had not an examination showed it to be epithelioma.

She was kindly referred to me by Dr. George R. Fowler, and treatment was begun early in July; from three to seven minims of the mixed toxins were injected into soft parts of chin which were involved in the disease. Within two weeks the ulcer had nearly healed, and within three weeks it had entirely healed and the parts almost regained their normal appearance. The floor of the mouth also showed a striking improvement. This improvement unfortunately did not continue more than a few weeks, and then a change for the worse appeared, and the injections no longer seemed to control the disease. A number of other cases of carcinoma, including epithelium, showed striking but only temporary improvement. I have seen very great œdema of the arm, caused by recurrent cancer of the breast, disappear with astonishing rapidity after two or three injections.

My feeling as regards the treatment of carcinoma with the toxins has, up to the present time, been very conservative, and until further experiments have been made I should not advocate its general adoption.

The increasing number of well-authenticated cases of carcinoma that have been permanently cured by attacks of accidental erysipelas, as well as the undoubted antagonistic action I have observed in my own cases treated with the toxins, should make us extremely hopeful that, in the near future, some of the success that has been achieved in sarcoma may be extended to carcinoma.

This is not the time nor place to attempt an explanation of this curative action of these germs. It would bring up the whole discussion of the etiology of cancer, a question surrounded by almost innumerable obstacles, and not yet settled to the satisfaction of the majority of the profession. Personally, I believe the evidence at present strongly in favor of the microparasitic theory of the origin of both sarcoma and carcinoma. Accepting this theory, the explanation of the action of toxins on malignant tumors is very easy; on any other theory I believe an explanation impossible.

Results with others who have Tried Toxins in the Way I have Recommended, and Using the Same Preparations.—At the American Surgical Association, at Washington, last May, in the course of the discussion, Dr. Keen stated that he had had no beneficial results in several cases that he had treated with the toxins. In my reply I stated that, up to that time, I had had the greatest difficulty in getting a stable preparation and one that could be relied upon for any length of time. The results that I reported at the time only followed persevering and often prolonged efforts, using many cultures differing greatly in value. It should be remembered that up to that time I had not recommended the general use of the toxins, and only at the request of a few surgeons whom I personally knew, was any sent for trial. It is clearly unfair to allow the results of a few such imperfect experiments to stand as a test of the value of the treatment.

Fortunately, since that time, with the help of Mr. B. H. Buxton, who has, during the past year, devoted a large portion of his time to investigating this subject, and aiding me in perfecting the preparation, it has been found possible to obtain a preparation of the mixed toxins sufficiently stable to render accurate dosage possible. It is much more effective than any I had hitherto used, due to the increasing virulence of the streptococcus caused by passing it through a series of rabbits.

The method of preparation I will refer to more in detail later, but at present I wish to refer to a few cases to prove that like good results can be obtained from the treatment in other hands than those of its author.

Dr. R. Tilly, of Chicago, in a letter dated August 16th, describes a case of sarcoma of the orbit, which he considered beyond operation, mostly on absolutely unfavorable prognosis. He tried at first the filtered toxins, with little or no benefit. He then used the unfiltered, including the bodies of streptococcus and B. prodigiosus, killed by temperature 58° C. The first three doses had no effect; the fourth gave a very severe chill and a temperature of 106° F. Within twenty-four hours the temperature was 97° F. The injections were continued about every other day for two or three weeks without much rise of temperature.

The tumor had steadily decreased, and August 16, 1894, it had entirely disappeared. I have not heard of the subsequent history of the case.

Dr. J. Alexander Moore, of Helena, Mont., has used the toxins in four cases. He obtained the preparations from me, and used them as nearly as possible in the way I have advised. His first case was a scirrhous cancer of breast, recurrent. The left lung and liver were involved. He began injections January, 1894. He states that the disease was undoubtedly restrained locally for some time, but owing to the advanced stage and generalization the treatment was discontinued.

Case II.—Epithelioma involving entire lower lip, two years' history. Growth ulcerating. Injections for above three weeks failed to produce any decrease in size.

Case III.—January 15, 1894. The patient, aged thirty-one, female. Recurrent, small, round-celled sarcomata of supra-clavicular region. Operation had been done May, 1893. Recurrence in two months followed. Injections with toxins of erysipelas and prodigiosus were begun January 15, 1894, and continued every two or three days until February 15th; at that time the original tumors, several in number, had entirely disappeared, but other new ones appeared.

The patient lived at a distance from town, and the treatment could not be given with regularity. On September 15, 1894, there were five small nodules

[1] Material drawn with aspirating needle was examined by Dr. Ferguson and he believed it to be sarcoma.

[2] A tumor in the left lumbar region broke down under the injections in sternal tumor and discharged material that could not be differentiated from that coming from sternal tumor.

Later Note.—January 15, 1895. A recent examination of scrapings from sinuses in sternum and back, by Professor E. K. Dunham, shows that both tumors were probably of tubercular origin. The effect of the toxins is in harmony with the well-known effect of actual erysipelas upon tubercular lesions of skin and glands referred to by Maurtac.

to be felt at site of former tumors. Dr. Moore writes: "The injections, when prosecuted with vigor, have never failed in this case to reduce or obliterate the tumors." When the nature of these tumors—small round-celled sarcoma, the most malignant type—is considered, the efficacy of the toxins cannot be doubted.

Case IV.—Male, aged thirty-one, tumor, size of a goose egg, attached to right mastoid bone, and not adherent to skin. The lymphatics were enlarged and indurated. The growth had been noticed two months. Treatment was begun April 4, 1894; very good reactions followed. There was some breaking down of tumor. August 20th, the tumor had entirely disappeared. Two small lymphatics could still be felt just above clavicle, but these were gradually becoming smaller. It is true, no microscopic examination was made in this case, but the case had been examined by other physicians of skill and experience.

Dr. Moore writes: "I am quite satisfied as to the effect of inoculation with the toxic products of erysipelas and B. prodigiosus in sarcoma, but only reasonably so in carcinoma."

Dr. George M. Kreider, of Springfield, Ill., surgeon to St. John's Hospital, writes me that he has used the toxins in three cases. The preparation used was the unfiltered, sterilized by 58° C., prepared by Mr. Buxton, the same as used by myself in the case reported.

One case was an inoperable sarcoma of the ilium of unusual size, involving not only the ilium but surrounding tissues. He writes that the result was very striking, but owing to the prostration of the patient he was obliged to stop the treatment. "Two hundred grammes (6¼ ounces) sloughed out, and it would seem certain that, had treatment been undertaken sooner, he would have recovered."

"The other cases of cancer have made gratifying progress, notably one case of uterine cancer. She was bedridden because of the swelling of the right leg and foot. The swelling disappeared entirely in three weeks, and has not returned, although the patient is on her feet continually. The pains and bleeding have also disappeared."

Dr. Thomas F. Rumbold, of San Francisco, has tried the toxins in a patient suffering from recurrent round-celled sarcoma, with the following result: In June, 1892, a tumor the size of a hickory-nut was noticed from the right breast. On July 7, 1892, it was removed and pronounced non-malignant, but within a few weeks it returned; a second operation was performed, taking off most of the breast. Within six months a third and fourth operations were performed, removing the whole of the breast but not the axillary glands. In July, 1893, the tumor again recurred. A very thorough operation was then made by Drs. Lane and Plummer, of San Francisco, and the axillary glands, which were then involved, were removed. A microscopic examination showed the tumor to be round-celled sarcoma. Since then three other operations, making eight in all, were performed. The sarcoma again recurred and was growing rapidly, when early in August, 1894, Dr. Rumbold wrote me requesting me to send him some of the toxins. The first injection was made August 14, 1894.

In a letter dated September 12th he says: "I am very glad to inform you that the case has progressed very favorably; in fact, the treatment has been a marvel in all respects to everyone who has seen the case. She is visited twice a week by a number of the most prominent physicians, who are greatly interested in the case and treatment. I do not think there is one-eighth of the tumor left, and I believe she would recover entirely without another injection; but, to make matters sure, I will continue the injections, as suggested in your letter."

A later letter states that the tumor had entirely disappeared. The patient was considerably weakened by the treatment and was suffering from persistent nausea.

Time will permit me to refer to only one other case outside of those of my own personal cases; but this case is too important to leave unnoticed. As the case was reported in full at the last meeting[1] of the Throat Section at the Academy, I need only give a very brief summary of the facts:

The patient was a boy, aged sixteen, with a very large spindle-celled sarcoma of the palate and pharynx. He was a patient of Dr. Walter B. Johnson, surgeon to Paterson General Hospital, of Paterson, N. J., and I was asked to see the case in consultation, in October, 1893. The physical examination at that time, made by Dr. Johnson, showed a tumor involving the entire soft palate, pillars of the fauces, region of the tonsils, and extending forward over the hard palate to within a half-inch of the incisor teeth, backward and downward, involving a portion of the pharyngeal wall, the whole base of the tongue, the epiglottis, and upper part of the larynx, but not extending to the true vocal cords. The infected parts were thoroughly impregnated with sarcomatous deposit, and the soft palate was increased to about three times its normal thickness. The growth consisted of cauliflower-like granulations, varying in size from a kernel of rice to a pea. The uvula was entirely destroyed; the cervical glands were enlarged. The patient had lost considerable flesh and strength, but was not cachectic. His weight was 86 pounds. He had difficulty in deglutition, and could not breathe through his nose. A microscopical examination made by Dr. James W. Williams showed the growth to be spindle-celled sarcoma. The tumor was so extensive that I expressed very little hope of any permanent benefit being derived from the toxins, but advised giving the treatment a short trial.

Dr. Johnson began, October 31, 1893, and continued the injections with occasional intervals for seven months. The reaction temperature following the injection varied between 99° and 103° F. The preparation used was the filtered toxins, grown separately and kept in separate bottles, mixing them at the time of injection. I had not then begun growing them together.

The result of the treatment is a constant, slow improvement, some of the sarcomatous tissue undergoing necrobiosis, some disappearing by absorption. In October, 1894, the patient weighed 107 pounds. He had had no treatment for three months, and the tumor had apparently entirely disappeared. (Two days ago Dr. Johnson wrote that there was one point in the mouth that looked slightly suspicious, and he decided to resume treatment for a short time. This same thing occurred once before, and quickly disappeared when the injections were begun.)

Since the reading of the paper another successful case has been reported to me by letter, and its great importance warrants inserting it here. The case was a patient of Dr. Judson C. Smith, of New York, Director of the Laboratory of the Post-Graduate Medical School and Hospital, and was treated by him personally. He writes: "You may refer to my case of sarcoma treated with the toxins as follows:

"Mrs. W——, aged twenty-eight, good family and personal history. Tumor of right side of neck about the size of an orange; had been growing one year. September 1st, when she came under my care, she was extremely emaciated, anæmic, and scarcely able to leave her bed. The tumor was beginning to break down, and the patient was septic, having a temperature of 103° F. She also had dropsy of lower limbs.

"On September 11, 1894, I made an incision under ether and scraped out a large mass of the tumor, but owing to the patient's poor condition no attempt was made to remove the whole mass, which was deeply seated, extending beneath the clavicle. The wound was packed with gauze, and four days later I began the injection of erysipelas and prodigiosus toxins. These were continued eight weeks. She has no sign of tumor now, has gained twenty-five pounds in weight,

[1] Medical Record, November 17, 1894.

and appears perfectly well. Microscopic examination proves the growth to be small round-celled sarcoma."

These results in the hands of independent observers are sufficient, I think, to confirm my own conclusions as to the value of the toxins in sarcoma.[1]

As to the question whether or not the toxins should be tried in all cases of inoperable sarcoma, there are many things to be considered. In the hands of men of experience, and very carefully administered, I believe the treatment to be attended with but little if any risk. My results show what may be accomplished in apparently the most hopeless cases; hence the importance, if possible, of giving such cases the benefit of a trial. If improvement is likely to occur, my experience has been that some evidence will present itself within two weeks after beginning the injections. It must be remembered that we have to deal with a very powerful, and as yet not thoroughly understood, agent, and it should be used with the greatest caution. Individuals vary greatly in their susceptibility to its action, and the minimum dose should be used at first. I have myself never had a death from it, though in one case I think the end was probably hastened. This was an enormous sarcoma of the scapula, involving clavicle, chest-wall, and a large portion of the humerus. The patient was very weak and emaciated, and the treatment should never have been attempted in a case so far gone. Only a single dose and a very small one (two minims) was given, the patient gradually grew weaker, and died four days later.

I will merely refer to another field for the use of the toxins, and one that seems to me likely to be very important, viz.: After primary operation for sarcoma, before recurrence has been allowed time to take place, the reasons for using the treatment in such cases are theoretically strong. If, as we have demonstrated, the toxins are able to destroy a large recurrent tumor, there is reason to believe their action would be more certain and effective in destroying the few and invisible germs of the disease left behind after operation. Since at least seventy-five per cent. of the cases do recur after primary operation, the importance of this field is apparent.

Method of Preparation of the Toxins.—To make the toxins of erysipelas and prodigiosus, ordinary peptonized bouillon is put into small flasks, containing 50 to 100 c.c., which, after proper sterilization, are inoculated with the streptococci of erysipelas and allowed to grow for three weeks at a temperature of 30° to 35° C. The flasks are then inoculated with B. prodigiosus, and the cultures allowed to grow for another ten or twelve days at room temperature. At the end of that time, after being well shaken up, the cultures are poured into sterilized glass-stoppered one-half ounce bottles, and heated to a temperature of 50° to 60° C. for an hour; sufficient to render them perfectly sterile. After cooling, a little powdered thymol is added as a preservative, and the toxins are ready for use. The toxins when prepared in this way are very much stronger than when filtered through a Pasteur, Chamberland, or Kitasato filter, the active principles contained in the germs themselves being preserved. If, as is sometimes the case, the preparation is found to be too strong to use with safety, it can be diluted with glycerine or sterilized water.

The best method of making the bouillon is to soak a pound of chopped lean meat overnight in water. In the morning strain it through a cloth, make up to 1,000 c.c., and boil for one hour. Then filter through a cloth, add peptone and salt, neutralize and boil again for an hour. The bouillon will then pass through filter-paper perfectly clear, and be ready to put into the flasks. It is not, however, necessary to neutralize the bouillon, as the streptococci will grow even more readily in acid bouillon, and the resulting preparation is, if anything, stronger than when neutralized bouillon is used.

In order to keep up the virulence of the cultures they are put through rabbits in the following way: The hair of the ear is clipped close with a pair of scissors, and the skin washed with weak carbolic acid, and then sterilized water. A minute quantity of a bouillon culture, forty-eight hours old, is then injected subcutaneously in four or five different places in the ear. Forty-eight hours later, after again washing the ear with carbolic acid and sterilized water, a flat needle sterilized in the flame is inserted under the skin at or near a point of inoculation, and the layer of the skin cut off with a sharp sterilized scalpel. The piece of skin is then rubbed well over the surface of an agar tube with a thick platinum-wire needle. After twenty-four hours in the incubator the colonies of streptococci will show as minute white specks, and from them a pure culture can be obtained. If the agar is made with seventy-five per cent. of bouillon and twenty-five per cent. of urine the streptococci will grow more freely than if bouillon alone is used. For the above brief but clear description of that preparation of the toxins, that up to the present time has proved most efficacious, I am indebted to Mr. B. H. Buxton. The dose of this preparation varies from one to eight minims; I have had a temperature of 105° F. follow the injection of two minims. I usually begin with the minimum dose and gradually increase until the desired reaction, *e.g.* temperature 103° to 104° F. is reached.

In concluding, I wish to briefly summarize my cases thus far treated. Up to May 31, 1894, I had treated with mixed toxins twenty-five cases of inoperable sarcoma, eight of inoperable carcinoma, and three of sarcoma or carcinoma. In the cases of carcinoma I had had marked improvement in a number of cases, but no cures. The cases were all very advanced recurrent tumors. In sarcoma I stated that there were six cases in which I considered there was a reasonable hope of permanent cure. Six months have passed since then, and none of the six cases have shown any recurrence. Of two other cases which were merely mentioned among the tabulated cases as improving, one has gone on to entire disappearance of the very large tumor and promises to be a cure, and the other, a six-times-recurrent sarcoma of hand, is in perfect health at present, nearly two years since the beginning of the treatment. Since May 31, 1894, I have treated twenty-four cases of malignant tumors, all inoperable and mostly recurrent, with the mixed toxins. Of these cases thirteen were sarcoma and eleven carcinoma. In many of the cases of carcinoma the injections had an undoubted retarding influence, and in some of the cases the improvement was extraordinary, but in no case did the tumor entirely disappear. In the sarcoma cases the effect was far more marked, and although in a number of the cases the disease was so far advanced that there could be no possible hope of recovery, still the powerful controlling influence of the toxins was demonstrated, and had the patient's general condition permitted a prolonged use of the injections, the result might have been otherwise.

In three of the thirteen cases the sarcomas have entirely disappeared, and although no great length of time has elapsed, the results in my older cases make it improbable that relapse will occur. Of my total of thirty-eight cases of inoperable sarcoma, therefore, nine cases promise to be permanently successful. These can be briefly epitomized as follows:

Case I.—A twice recurrent inoperable sarcoma of the neck, with secondary growth, size of an egg, in tonsil. General condition extremely bad; given by Dr. W. T. Bull three or four months to live. Treatment with erysipelas (living cultures) began May 2, 1891. No treatment since October, 1891. Result:

[1] Since the paper went to press several additional successes in sarcoma in the hands of other surgeons have been reported to me by letter.

Tumor of neck practically disappeared. Tonsil tumor greatly decreased in size, and has still further diminished the past year. The patient regained his general health in a few months, and November 12, 1894, three and one-half years later, remains in good health.

Case II. *A Large Recurrent Sarcoma of Back and Groin.*—Treated at first with living cultures, later with mixed toxins. No recurrence twenty months after cessation of treatment; and nearly three years since beginning. (This case I have had the pleasure of showing you this evening.)

Case III. *Large Inoperable Sarcoma of Abdominal Wall and Pelvis.*—Treatment begun February, 1893. Result: Almost entire disappearance in two months. Patient has been in perfect health ever since, with no tendency to relapse twenty-two months later. (Exhibited at Academy of Medicine, November 15, 1894.)

Case IV. *Large Inoperable Sarcoma of Iliac Fossa.*—Almost entire disappearance of tumor. Treatment begun June, 1893. In good health August, 1894.

Case V. *Large Inoperable Sarcoma of the Abdominal Wall.*—(Exploratory operation by Dr. Maurice H. Richardson, of Boston. Microscopical examination by Professor Whitney, of Harvard Medical School.) Entire disappearance of tumor under two and one-half months' treatment. In perfect health, December 22, 1894, without trace of recurrence fourteen months after beginning of treatment.

Case VI. *Recurrent Sarcoma of Leg.*—(Dr. Bull's case.) Treated at the New York Hospital; later at the New York Cancer Hospital. Entire disappearance of tumor. No recurrence December 22, 1894, nearly one year later. (Exhibited at Academy of Medicine, November 15, 1894.)

Case VII. *Enormous Osteo-chondro Sarcoma of Ilium.*—(Dr. Shrady's case.) Treated at St. Francis and New York Cancer Hospital. Treatment begun March, 1894. Entire disappearance. No relapse December 22, 1894. (Since the reading of paper a portion of thickened tissue at site of old tumor was removed for examination, and no sarcomatous elements were present.) (Exhibited at Surgical Section of Academy, October 12, 1894.)

Case VIII. *Sarcoma of Hand, Six Times Recurrent.*—Growing rapidly February, 1893, when treatment was begun. Held in check eighteen months. Degenerated tumor tissue removed July, 1894. Patient has since gained twenty pounds, and is in perfect health without relapse December, 1894.

Case IX. *Sarcoma of Scapula and Chest-wall, Involving Larger Portion of Entire Left Half of Thoracic Wall.*—Entire disappearance in three and one-half months' treatment. In perfect health at present (January 13th), two months since treatment was discontinued. (Exhibited at Academy, November 15, 1894.)

With exception of the first, all of these cases were treated with the mixed toxins of erysipelas and bacillus prodigiosus, the streptococcus cultures having been obtained from a fatal case of erysipelas. That the bacillus prodigiosus plays a very important part in the action of the toxins on sarcoma, I have not only repeatedly demonstrated, by using the two singly and combined, but my conclusions have been verified by others. The prodigiosus toxins used alone have a marked effect in causing degeneration and absorption of sarcomatous tissues, but the combined action of the two toxins is greater than when either is used alone. I have also found by experiment that sarcina used with erysipelas has a similar effect.

When we consider that all of the cases reported were hopeless, not only from an operative stand-point, but from any hitherto known method of treatment, that in every case the diagnosis was established according to the most approved principles of medical science, confirmed clinically by the most eminent surgeons, and microscopically by leading pathologists, we are in a position to understand the importance of this subject.

I cannot sufficiently express my indebtedness to Dr. Alexander Lambert and Mr. B. H. Buxton for invaluable bacteriological assistance, and it is largely due to their most careful and skilful work that the preparation of the toxins has been so far perfected as to make accurate dosage possible.

Note.—By an unfortunate mistake the photographs illustrating the cases were omitted.

DIAGNOSIS AND TREATMENT OF STENOSIS OF THE PYLORUS.[1]

By MAX EINHORN, M.D.,

NEW YORK.

Before beginning the proposed subject, I would like to say a few words regarding the expressions relating to this field, namely, "dilatation of the stomach," "anatomical and clinical dilatation of the stomach," "ectasia ventriculi," "insufficiency of the stomach."

As is well known, the term "clinical dilatation of the stomach" is used by most authors wherever there is stagnation of food in the stomach. The real meaning of the word "dilatation of the stomach," or "ectasia ventriculi," however, is merely a signification for the dimension of that organ. This explains the frequent misunderstandings caused by these expressions. Some speak of dilatation of the stomach as soon as the limits of this organ are found enlarged; some, however, only in those instances where there are found remnants of food in the morning in the fasting condition. Rosenbach,[2] therefore, suggested the term "motor insufficiency of the stomach" in order to designate that the transportation of food from the stomach into the small intestine is at fault. In an article which recently appeared in the *Deutsche Med. Wochenschrift*, Boas[3] was of the opinion that the expressions "dilatation of the stomach" or "ectasia ventriculi" should not be used at all. Instead, he suggested the terms "gastric insufficiency of the first and second degrees." The first degree corresponds to the atonic condition, the second to the stagnation of food. Although, like Boas, I am fully convinced of the importance of differentiating between cases of stagnation of food, and such in which the transportation of the chyme is only slightly retarded, I do not, however, believe that we ought to discard the expression "dilatation of the stomach," nor that the proposed term, "gastric insufficiency of the first and second degrees" is well selected.

"Dilatation of the stomach" is a term for the condition of the volume of the stomach, and signifies an enlargement of its dimensions. Such conditions not only do exist, but form an every-day occurrence. There is, therefore, no reason for discarding the word "dilatation of the stomach." Whether this enlargement of the dimensions of the stomach has been formed by physiological or pathological processes, and whether it creates abnormal conditions or not, will have to be investigated in every single case.

The term "insufficiency" or "mechanical (motor) insufficiency of the stomach," signifying a retardation in the transportation of the food from the stomach into the intestine, appears to me ill chosen; for the word "insufficiency," or "mechanical insufficiency of the stomach," does not clearly point out the condition of the transportation of chyme from the stomach into the intestines. Moreover, the term "mechanical insufficiency of the stomach" means that the fault for the non-transportation of food lies in the stomach, which is not the case in most instances.

When there is a stenosis of the pylorus, there can be no fault found with the stomach, its muscles accomplish their duty, sometimes even to an increased degree, but

[1] Read before the German Medical Society of New York, November 5, 1894.

[3] Boas: Deutsche Med. Wochenschr., 1894, N. 28, p. 576.

the chyme fails to pass the narrowed outlet. This is the reason why the term "insufficiency of the stomach" does not appear to suit these conditions.

Analogous to the expression "ischuria," which signifies an abnormal collection or stagnation of urine in the bladder, without stating the reason for this condition, the word "ischochymia"[1] might be applied in order to designate an undue stagnation of chyme in the stomach. Thus, "ischochymia" will embody a complex of symptoms without stating the cause. The latter will have to be discovered and further determined in each case. As you will see later on, stenosis of the pylorus is the main factor of most of these conditions.

Surgery, as well as medicine, has made great progress during late years. The greatest achievements, however, are found where the surgeon and clinician go hand in hand in performing their task. The clinician endeavors to discover the hidden, deep-seated malady and its nature; the surgeon tries to penetrate this region and to do away with the evil by means of the knife. This co-working of surgeon and clinician has accomplished the most fruitful results in the treatment of various affections of the brain (tumors, abscesses) and in the treatment of intra-abdominal organs.

The stomach, particularly, frequently requires surgical interference, and the benign stenosis of the pylorus—a malady which had been, until fifteen years ago, absolutely mortal—is now entirely cured with the aid of the knife!

Stenosis of the pylorus—no matter whether the same be caused by a contracting cicatrix after an ulcer, or by a benign hypertrophy (new-formation of muscles and fibres to such a degree that the lumen is highly obstructed) of the pylorus—or whether the same originates from a malign tumor, must be given to the surgeon for operative interference. The clinician has the task to diagnosticate the stenosis of the pylorus with the greatest possible precision at an early stage, and to determine, if possible, the nature of the stenosis, *i.e.*, whether benign or not.

In regard to the literature of this subject I refer to the excellent paper of S. Mintz,[2] "On the Surgical Treatment of the Diseases of the Stomach," recently published in the *Zeitschrift für Klinische Medicin*. According to the carefully gathered statistics of this author, the number of operations thus far performed for cicatricial stenosis of the pylorus is as follows: 1. Pylorectomy has been performed on 31 patients, with 54.8 per cent. recovery. 2. Gastro-enterostomy performed on 54 patients, with a recovery of seventy-one per cent. 3. Pyloroplasty has been performed on 31 patients, with 77.4 per cent. recovery. 4. Loreta's operation (digital divulsion of the pylorus) performed on 23 cases, with fifty-nine per cent. recovery.

In these statistics are included three cases of gastro-enterostomy which had been reported by Mintz himself, and two cases of pyloroplasty which have been performed in this country by N. Senn,[3] and published in the MEDICAL RECORD of 1891. In this paper Senn, besides the two cases of pyloroplasty, describes thirteen cases of malign stenosis in which he had performed gastro-enterostomy, and advocates surgical interference in all cases of pyloric stenosis.

In the past four or five years I have had the opportunity to observe a considerable number of cases of stenosis of the pylorus, both of benign and malign nature. Quite a number of these cases have been operated upon by renowned surgeons of this city, and have thus offered the opportunity of verifying the diagnosis by the autopsy *in vivo*. It appeared to me worth while to report several of these cases, and thereafter to describe the diagnostic points as they could be elucidated from them. In this way, I trust, I shall be best able to draw your attention to these affections.

[1] Ischochymia (from ἰσχεῖν = detain, and χυμός = chyme).

A. The Benign Stenosis of the Pylorus.—CASE I. September 24, 1891.—K——, aged about twenty-eight, merchant, was all right until about seven years ago. At that time he got sick suddenly, with severe pains in his stomach, after drinking ice-water while in an overheated condition. Since then patient was troubled with periodical attacks of severe pains in his epigastric region. These were accompanied, at times, by vomiting. At the beginning patient felt perfectly well between the attacks for long intervals. Soon, however, the attacks grew more painful and longer, whereas the intervals of freedom were of shorter duration. Since January, 1891, patient suffered constantly and had to remain in bed. The pains appeared independent of food, and seemed rather to appease by partaking of same for a short time. There frequently was (once or twice a week) vomiting, but it never contained any blood. Sometimes, however, there was in the vomit food from the previous day. These were the anamnestic points Dr. Alfred Meyer, of this city, was kind enough to give me, when he called me in consultation to this patient.

Present condition: Chest organs intact; epigastric region sensitive to pressure, but not especially painful. There was no splashing sound at the time of examination, and in this way the size of the stomach could not be made out.

The examination of the stomach-contents one hour after Ewald's test-breakfast showed: HCl +; acidity = 160; no lactic acid. The quantity obtained measured about 150 c.c. and did not contain any food from the day previous. At that time the diagnosis fluctuated between some functional nervous affection of the stomach, causing high hyperacidity—and at times continuous sucorrhœa—and stenosis of the pylorus. I advised the use of large doses of alkalies and the application of intra-gastric galvanization. This treatment was carried out for some time with apparently good result. Soon, however, the old pains reappeared, and were accompanied by severe spells of vomiting. In the vomited matter there were once found some grapes, of which the patient had partaken three or four days previously. At the second consultation with Dr. Alfred Meyer we made the diagnosis with great probability of stenosis of the pylorus, caused by cicatricial tissue after an ulcer, and advised an operation.

The patient was subsequently operated upon by Dr. F. Lange: a small, egg-shaped tumor of the pylorus was found stricturing the canal in a high degree. Heinecke-Mikulicz's pyloroplasty had been resorted to. Patient recovered and has remained perfectly well since.

CASE II. January 1, 1893.—Miss Margaretta L——, aged thirty-eight, nurse, began to be troubled with pains in her stomach fourteen years ago. There was lack of appetite; after meals nausea and, sometimes, vomiting. About ten years ago patient came to this country, where her condition grew worse: there were more pains and the vomiting appeared more frequently. About five or six years ago patient noticed in her vomit foodstuffs of which she had partaken two to three days previously. Five years ago patient was under treatment for five months in the German Hospital: first regular rest-cure for ulcer, then lavage. Patient had then gained thirty pounds. Soon, however, her condition grew worse again, and in the summer of 1892 patient had to return to the German Hospital. She then passed large quantities of dark-colored blood with her stools. Patient remained in the Hospital for three weeks and was again subjected to a regular rest-cure for ulcer. Patient then left for the country and rallied in some respects. She suffered, however, with pains and vomiting from time to time.

When patient came to see me on December 31, 1892, her complaints were principally the almost constantly persisting pains and the frequent appearance of vomiting spells. For quite a while patient had made

use of lavage of the stomach. This procedure, although it gave temporary relief lasting a short while, did not, however, change her condition for the better. Bowels were always constipated.

Present Condition.—Patient, of frail structure, has a very thin layer of panniculus adiposus. The mucous membranes are quite pale. Tongue only slightly coated. Chest organs intact. The stomach extends almost to the symphysis; this can be easily demonstrated by means of the easily produced splashing sound and by gastro-diaphany. The small curvature lies about two finger-widths above the navel. The epigastric region is not painful to pressure. No tumor. Right kidney movable. Liver not enlarged. The urine contains neither sugar nor albumin.

January 1, 1893.—The examination of the stomach-contents one hour after Ewald's test-breakfast shows: HCl +, acidity = 74, lactic acid not present. The contents obtained have a reddish color and reveal food from the previous day. Red blood-corpuscles cannot be discovered microscopically; Teichmann's test for hæmin gives, however, a positive result.

For a week the patient uses lavage in the evening and is directly gastro-galvanized every morning in the fasting condition. Under this *régime* the pains subsided considerably; the examination of January 9th, however, showed that the stomach was not empty in the fasting condition, and contained food from the previous day. The quantity of the stomach-contents was not large (about 150 c.c.) and showed the following characteristics: HCl +, no pieces of meat visible, but amylaceous substances can be easily recognized, especially rice which had been taken on the foregoing day.

January 11 and 13, 1893.—The stomach is examined in the fasting condition and the same result obtained as on the 9th. On these two days the stomach has been transilluminated and its exact position ascertained. The stomach extended to the symphysis and the transilluminated zone extended from there to about two finger-widths above the navel.

The diagnosis of a benign stenosis of the pylorus was made, probably as the result of a cicatricial thickening after an ulcer, and the patient sent to Dr. F. Lange for an operation.

Dr. Lange operated on the patient on January 23, 1893. The stenosis was found directly behind the pylorus at the beginning of the duodenum. Heinecke-Mikulicz's pyloroplasty was performed and the patient recovered after a short period of confinement. Since then she has remained free from pains.

March 13th.—I again examined the patient one hour after Ewald's test-breakfast. There were *no* food remnants from the previous day; HCl +, acidity = 78.

March 20th.—Patient was examined in the fasting condition. The stomach was found empty; the gastro-diaphany, however, showed that the boundaries of the stomach had not changed.

October 29th.—Patient was examined one hour after Ewald's test-breakfast: HCl +, acidity = 40; no food remnants from the previous day. Patient feels well, is not troubled with pains, and has not vomited since the operation. She has gained in weight and is able to attend to her regular vocation.

Case III.—Louis L——, forty years of age, lawyer, began to be troubled with his stomach in the summer, 1891. The patient was attacked with pains after meals; these pains lasted for ten days and disappeared suddenly. There was no vomiting. For six months patient felt well, not having any pains whatever; he noticed, however, that he used to get tired quicker than heretofore. In the winter of 1892 (February) patient had anew an attack of pains lasting more than a month. During this attack patient vomited twice. Patient felt well until July, whereupon he had a fresh attack of pains extending over two to three weeks, with four vomiting spells. On account of the severe pains patient could not lie quietly, but had to walk frequently to and fro in his room. In December, 1892, patient had another attack lasting until February, 1893. Patient then had to vomit frequently (nearly every other day). Patient had never vomited any blood. Since the beginning of the sickness the bowels were constipated.

On January 27, 1893, Dr. Charles Simmons called me in for a consultation and entrusted me with the treatment of the patient (for which courtesy I am greatly indebted to him).

When I first saw the patient he presented the picture of a very sick man in agonies of pain. Patient looked pale and emaciated; he asserted that he had lost about forty pounds in weight since the beginning of his ailment, and complained of a feeling of constriction in his abdomen and of shortness in breathing; he further complained of vomiting large quantities of fluid and of obstinate constipation. During the last fourteen days patient had taken large doses of opium; he was, however, very rarely entirely free from pains.

The examination showed: Chest organs do not reveal anything abnormal. Tongue slightly coated; pulse, 90; temperature, 98° F. The whole abdomen is more or less bloated and quite tense. In the gastric region no splashing sound can be produced. No tumor can be felt. The fluid which the patient vomited a few hours ago showed many blackish flakes swimming in it, contained a great quantity of free HCl, gave no reaction for lactic acid, and had an acidity = 90.

Patient was instructed to have a small meal (well-scraped meat, oysters, milk, crackers) every two hours. The quantity of liquids was reduced (patient was allowed to take only 150 c.c. at the time). Besides, oil clysmata were administered. Under this treatment patient felt somewhat better, although his ailment, on the whole, did not change. On January 29th patient was instructed not to take any food after his eight-o'clock evening meal until the next morning. On January 30th, at 8 A.M., when fasting, the tube was inserted into the stomach and two quarts of liquid withdrawn. The stomach was then washed with lukewarm water. Patient felt exceedingly well after this lavage.

The withdrawn gastric liquid was analyzed; in this sample, too, there were the blackish flakes mentioned above. The examination showed: HCl +, acidity = 88, lactic acid not present; peptone +, propeptone +, rennet and pepsin +, erythrodextrin +.

Microscopically: No particles of meat can be found; amylaceous grains are present in considerable quantity, yeast-cells, and bacteria. Teichmann's test for blood shows the absence of hæmin.

Thus the withdrawn liquid consisted principally of gastric juice and of remnants of food taken the previous day.

February 1, 1893, at 10 P.M., the stomach of patient was thoroughly washed out; during the night patient did not partake of anything, and on February 2d, at 8 A.M., the stomach was examined with the tube and a small quantity of liquid withdrawn (150 c.c.). The examination of this gastric liquid showed: HCl + ; both ferments present; acidity = 70.

One more week patient was treated with lavage. He felt better and could walk out-doors. The pains, however, persisted, although they were less severe, and the stomach was never empty in the morning, and contained more or less large quantities of liquid with food remnants.

February 11th, 13th, and 15th.—Intra-gastric galvanization was applied without, however, materially improving patient's condition. The diagnosis of benign stenosis of the pylorus was made and an operation warmly recommended.

Dr. F. Lange undertook the operation on February 22d. The pylorus was found constricted in a high degree. Heinecke-Mikulicz's pyloroplasty was performed, and after a month's confinement patient left the clinic. Although patient was now able to partake

of a more varied and coarse diet without vomiting, he notwithstanding constantly complained of pains and had to resort to opium.

On March 30th, the stomach of patient was examined one hour after the test-breakfast: HCl+; no lactic acid; acidity = 120, no remnants of food from the previous day. It was supposed that this high degree of acidity might be the cause of the pains. The patient was, therefore, instructed to take half a teaspoonful of bicarbonate of soda three times a day, two hours after meals. This worked like a charm; the pains entirely disappeared and patient began to gain fast in flesh. After six months medication with the soda the patient discontinued its use and felt perfectly well without it. Patient attends to his business and has gained seventy pounds since the operation.

Case IV.—Mrs. P. L——, forty-three years of age, mother of three children. Her mother died of cancer. Patient is suffering for six years. The ailment began with diarrhœal trouble lasting for two years. (Patient is not able to state whether the stools were of dark color.) Since four years cramps in the stomach. The pains are extremely severe; there is relief after belching or flatus. Never had any jaundice. For the last two years intense burning in the stomach with frequent vomiting spells. Never vomited any blood. During the night the pains are extremely severe and disturb sleep. Patient during last months lost considerably in weight (about thirty pounds). With this anamnestic record the patient was sent to me, through the kindness of Dr. Willy Meyer, for examination and diagnosis.

Present Condition. February 11, 1894.—Chest organs intact. The palpation of the abdomen reveals a small cylindrical tumor of the size of an egg, situated to the right of the navel. This tumor is easily movable in all directions and has an even surface. A splashing sound can be produced in the gastric region to one to two fingers' width below the navel. The gastric region is not painful to pressure. The liver is not enlarged.

February 12th.—After lavage the patient is examined with the gastro-diaphane; the stomach is found considerably enlarged and occupying a low position.

February 13th.—The patient is examined with the tube one hour after a cup of tea without bread (the patient being in the fasting condition with the exception of the tea). The stomach contained about 300 c.c. of a slightly greenish liquid (presence of bile), in which were only a few remnants of food (several bread particles) from the previous day. The analysis showed: HCl+, acidity = 42; free HCl = 24; lactic acid = 0.

The patient was then treated for a week with lavage and chloral hydrate at the New York Post-Graduate Hospital; there was, however, no material improvement in the condition of the patient.

On February 20th the patient was examined one and one-half hour after Ewald's test-breakfast: HCl+, acidity = 50; no lactic acid. The obtained gastric contents amounted to 300 to 400 c.c. and contained food from previous days; for instance, rice, which had been taken on the previous night, and several grape-skins, which had been taken three days before. This time no bile could be detected.

The diagnosis (of benign stenosis of the pylorus) was made and the patient operated on by Dr. Willy Meyer. After opening the abdomen the tumor, which proved to be the thickened pylorus, was resected.[1] The duodenum was then inserted into the stomach by means of Murphy's button. The patient passed an undisturbed convalescence, evacuated the button in her stools during the third week, and has since been well. She has gained twenty pounds and has had no pains whatever.

The resected, highly thickened, and stiff pylorus could not be macroscopically discerned from a cancerous organ; the microscopical examination, however, showed that it was merely an hypertrophied pylorus.[1]

Epicrisis.—In Case I. (K.), at first, the diagnosis of stenosis of the pylorus could not be made, as the ischochymia was absent. Later on ischochymia appeared (there were in the vomit food remnants from previous days), and this in combination with the failure of every rational therapeutic means, pointed with great probability to the diagnosis of benign stenosis of the pylorus. The operation confirmed this diagnosis. In the other three cases the diagnosis was immediately made with certainty. Only in one case (Mrs. P. L.) could the pylorus be palpated as a small oval tumor (of small hen's egg size); in all others the pylorus could not be felt. All four cases revealed a long period of sickness (extending from two to fifteen years), in which the appearance of pains played the greatest part. Although at first, either with or without therapeutic aid, there appeared ameliorations, these periods of euphoria, however, were again and again interrupted by fresh attacks of sickness. They constantly became more violent and of longer duration, and the pains subsided only after an artificially induced or spontaneous vomiting spell. Still later, when the ischochymia had developed to a higher degree, not even vomiting brings entire relief, and the patients are subjected to the greatest pains and sufferings. They emaciate quickly, and if there is no radical help brought at this period, go to a sure death by hunger. In all these four cases which have been operated upon a radical cure has been accomplished. All four gained considerably in weight, had no pains, no digestive troubles whatever, and could attend to their daily vocations in life. They all lived like "new-born," if I may be allowed to use this expression. In two of these patients we convinced ourselves, by means of several experiments, of the prompt forwarding of the contents from the stomach into the intestines in their new period of life. The chemical condition was not markedly changed; the gastric volume in the two patients was not appreciably smaller six months after the operation.

Besides these four cases of benign stenosis of the pylorus on which operations had been performed, I had opportunity to diagnose this condition in six other patients. I may be permitted to describe three of them.

Case I. February 14, 1894.—N. C. S——, forty-eight years of age, merchant, suffered with digestive troubles for the last twenty years. Since March, 1893, his symptoms became more aggravated. For several weeks patient vomited every day. There were pains in the scrobiculus, radiating toward the right side; frequent eructations of gas; constipation. Patient had lost considerable in weight. By means of lavage, which patient had himself learned to use, his condition improved. The pains, however, did not disappear entirely.

Present Condition: Palpation of the abdomen shows sensitiveness at the right hypochondriac region. To the right and somewhat above the navel, one can feel a cylindrical tumor of the thickness of the thumb; the same is one and a half inch long, presents a smooth surface, and can be easily moved in all directions. A splashing sound can be produced in the gastric region, which extends to one hand's width below the navel. In shaking the patient one can hear in his immediate neighborhood a distinct succussion sound. Knee reflex present. Urine contains neither sugar nor albumin.

February 15th.—Examination with the tube one hour after Ewald's test-breakfast. The contents obtained amount to over a quart and contain, besides the roll, food from the previous day, as for instance, rice, spinach, and other substances. Chemically: HCl +, no lactic acid; acidity = 124; erythrodextrin + much; rennet +; peptone and propeptone present. Patient is instructed to have with his supper some rice besides

[1] Heinecke-Mikulicz's operation could not be done in this case: 1, on account of suspicion of cancer; 2, because the lumen was too narrow and the thickening of the walls of the pylorus too considerable.

[1] The wall of the pylorus, measured, after the specimen was preserved in alcohol for about nine months, in thickness 1½ ctm.

other food (meat, etc.). On the following morning, February 16th, patient is examined in the fasting condition. About a pint and a half of gastric contents are obtained; the same reveals a considerable amount of undigested food, namely: rice, bread particles, asparagus, etc., but no meat. The chemical examination shows: HCl +; acidity = 90: no lactic acid; erythrodextrin + much; starch +.

The salol-test of Ewald revealed the appearance of the salicyluric acid in the urine in the third hour after partaking of the substance.

February 18th.—Patient is again examined in the fasting condition, and a pint and a half of chyme obtained; the same shows the above-described chemical properties, and one finds therein microscopically yeast cells and various bacteria. After a thorough washing about 500 c.c. of water are left in the stomach and the patient examined with the gastro-diaphane. The transilluminated zone almost reached to the symphysis and extended upward to about three fingers' widths above the navel, and to the right to about a hand's width from the navel. The transilluminated red zone was interrupted at the upper right angle by a small shadowy figure of a thumb's size.

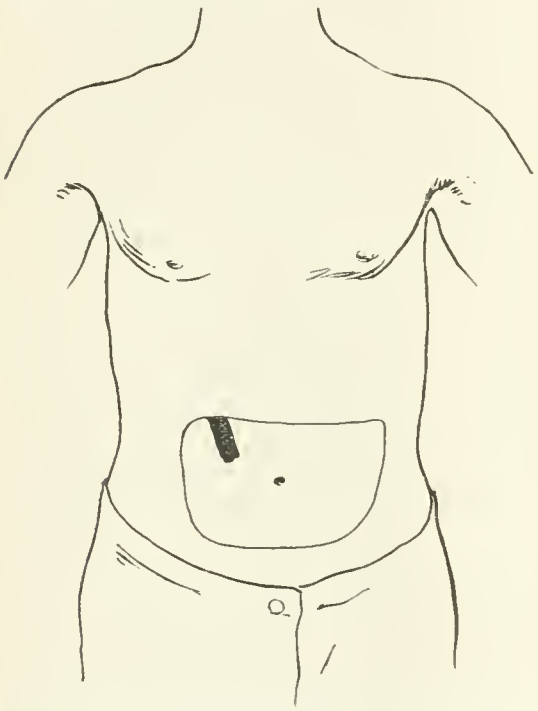

Fig. 1.—Result of Gastrodiaphany in patient N. C. S——. This shadowy figure may perhaps be the pylorus adhering to the front wall of the stomach, and around which to the back lies the expanded stomach.

February 19th.—Patient is again examined in the fasting condition and the same results obtained as on the 18th as regards the ischochymia. The diagnosis is made: Benign stenosis of the pylorus and surgical interference advised.

Patient returned to his native city, St. John, and has not been heard from since.

Case II. May 17, 1894.—William U——, thirty-four years of age, merchant, is suffering for the last eight years from digestive troubles. They consist of frequently appearing attacks of severe pains and spells of vomiting. Appetite always good; bowels constipated. Patient had been variously treated in this country and in Europe, but without marked result. He was in Carlsbad, thereafter in a sanitarium in Switzerland, where he had been subjected to a rigorous milk diet. At Mont Clemens patient had been given a thorough rest-cure by Dr. Kniffler and nourished merely by the rectum for some time. Later on patient was treated by massage and percutaneous faradization of the stomach. All these therapeutic measures, however, could only temporarily alleviate the condition of the patient, and did not change in any way materially the run of the disease. Patient asserts that he had lost fifty pounds in the beginning of his ailment; lately his bodily weight remained the same. The amount of urine constantly averaged for the last months about three pints for twenty-four hours. Patient used lavage of the stomach for several years. Notwithstanding these washings the pains were at times so intense that patient had to take refuge in morphine.

Through the courtesy of Dr. Kniffler patient came to me for diagnosis.

Present Condition: Tall and stately man, looks quite thin. The tongue is thickly furred. Chest organs intact. The examination of the abdominal organs shows splashing sound, extending from the left margin of the ribs to about two fingers' width above the symphysis. No pain to pressure. No tumor. Liver not enlarged. Knee reflex present. Urine contains neither sugar nor albumin.

May 18th.—Patient is examined with the tube in the fasting condition, and a pint and a half of gastric fluid obtained. Food remnants—principally starchy substances—are easily recognized therein. Chemically: HCl+; no lactic acid; acidity = 70. Microscopically: Yeast cells, grains of starch in considerable quantity, no fibres of meat. Patient is instructed to eat meat, bread, and rice for his supper, not to wash out his stomach, and to take Ewald's test-breakfast on the following morning.

May 19th.—One hour after the test-breakfast two pints of gastric contents are obtained; besides bread particles one notices rice grains in considerable quantity and some spinach. The chemical analysis shows: HCl+; no lactic acid; acidity = 70, erythrodextrin+; peptone +; propeptone+. The salol test shows the appearance of salicyluric acid in the urine in the third hour after the partaking of the salol.

May 21st.—An hour after Ewald's test-breakfast patient is examined first with the gastrograph: 83 current-changes are marked within three minutes. Then the gastric contents are withdrawn by means of a tube. The quantity amounts to two pints. Besides the particles of roll one notices food remnants from the previous day. Chemically: HCl+; no lactic acid; acidity = 60; free HCl = 52.

May 22d.—When fasting, one pint and a half of gastric contents are withdrawn. With the naked eye one notices food remnants. Chemically: HCl+; acidity = 70; erythrodextrin +. The stomach is thoroughly washed out; then 500 c.c. of water are left within the stomach, and this organ examined with the gastro-diaphane. The transillumination zone begins two to three fingers' widths above the symphysis, and extends upward to a hand's width above the navel, and to the right three inches away from the navel. (See Fig. 2.)

The constant ischochymia (in the fasting condition food remnants and large quantities of gastric juice), which in this case was combined with hypersecretion, the presence of free HCl, and the long duration of the sickness, appear to leave hardly any doubt as to the diagnosis of a benign stenosis of the pylorus. An operation is warmly recommended. Patient returned home and I have not heard from him since.

Case III. October 4, 1893.—Mrs. Maria L——, about fifty-eight years of age, is suffering for the last eighteen years with severe pains in her stomach and frequent vomiting. These digestive troubles appeared periodically and alternated, at the beginning of the sickness, with long free intervals (once nine months, then half a year). Thereafter these intervals constantly became shorter, whereas the periods of suffering grew longer. For the last year patient was constantly suffering. The appetite is not poor, but the pains increase after meals and the patient must frequently vomit. There is frequent eructation of gas that smells badly. Patient often experiences an intense burning sensation at the scrobiculus. For nine months the

pains are so severe every evening that patient has to take refuge in morphia. Although this drug exerts a somewhat soothing effect upon the patient, it does not, however, relieve her from pain. Patient, within the last two years, has lost forty pounds and feels very badly. Bowels constipated. The secretion of urine diminished. Patient noticed in the vomit food from previous days. There was never any blood found either in the vomit or in the stools.

Present condition: Frail, very thin woman, with pretty large, protruded abdomen. Tongue thickly coated and smells badly. Lips are pale. The skin can be lifted in large folds; the panniculus adiposus has nearly disappeared. The chest organs do not present anything abnormal. The abdomen appears protruded in its lower part and gives the impression of a tumor. Palpation, however, fails to discover any tumor. Splashing sound present and can be produced way down to the symphysis, and quite a distance to the right of the navel. There is only slight pain to pressure in the scrobiculus. The right kidney is easily palpated during a deep inspiration. Knee reflex present. Urine contains neither sugar nor albumin.

The examination of the stomach by means of the tube reveals: There are in the stomach considerable quantities of badly-smelling, decomposed foodstuffs.

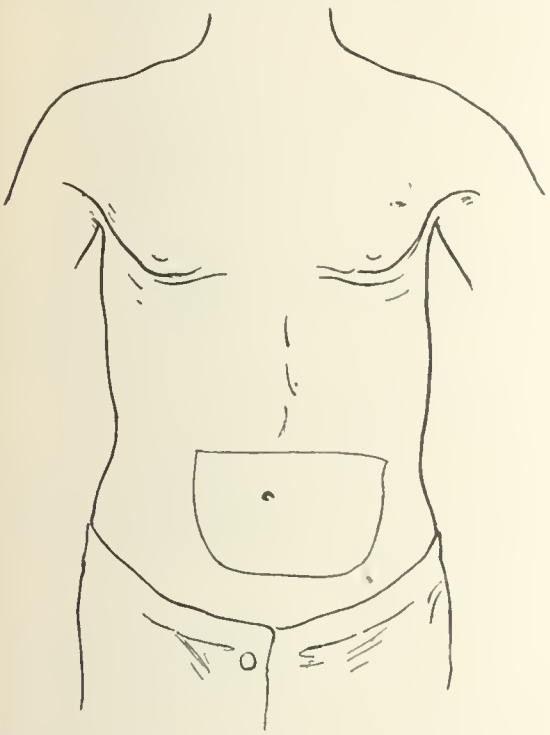

FIG. 2.—Result of Gastrodiaphany in patient William U——.

About four pints of the contents are withdrawn with great difficulty. The stomach could not be thoroughly cleansed at this first sitting; the tube again and again becomes obstructed, and the patient is too exhausted to stand the process of lavage any further.

The examination of the contents obtained showed: 1, Fetid odor; 2, absence of free HCl; 3, presence of lactic acid; acidity = 40; rennet present only in traces. Microscopically: A great number of bacteria, yeast cells, unchanged fibres of muscles, starchy grains, tyrosin crystals. Patient is advised to partake every three hours of small quantities (150 to 200 c.c.) of milk or kumyss with some crackers.

October 7th.—In the fasting condition the stomach contains over two pints of chyme, consisting of casein, particles of bread, spinach, and other foodstuffs, of which the patient had partaken four or five days ago. Chemically: HCl = 0, lactic acid +, acidity = 45, erythrodextrin + little, peptone +, rennet + traces.

This time again it was impossible to cleanse the stomach perfectly. Patient, then, for a week was treated with rectal alimentation; massage was applied to her stomach, and chloral-hydrate, 6 to 200, was given, a tablespoonful every three hours. The pains somewhat subsided, and patient felt quite some better.

October 17th.—The stomach is washed out in the fasting condition and a considerable quantity of chyme withdrawn. The same showed the following properties: Absence of free HCl; presence of lactic acid. The smell was not, however, as bad as in the beginning. Patient now, besides the nourishing enemata, received small quantities of light food by the mouth, and was given benzonaphthol. The washing of the stomach, which, thereafter, was practised only in the fasting condition, constantly showed the same result, namely, ischochymia, absence of free HCl, and presence of lactic acid. The abdomen became smaller, the pains more or less disappeared, and the patient did not lose in weight. She felt somewhat stronger, and was able to attend to some of her daily duties.

Taking into consideration the long period of sickness (eighteen years) and the absence of any tumor, the diagnosis was made of benign stenosis of the pylorus, and an operation advised. Patient, however, refused surgical interference on account of her advanced age.

The other three cases resemble cases of Louis L—— and William N—— so much, that a detailed account of them may be omitted. They all showed constant ischochymia with considerable quantities of gastric juice (hypersecretion), presence of free HCl, absence of lactic acid, a high acidity, and a long period of sickness.

Although these six cases, as far as I am aware, have not been operated upon, the diagnosis of benign stenosis of the pylorus, nevertheless, appears to me quite certain.

B. Malignant Stenosis of the Pylorus or Cancerous Stenosis.—Cancerous stenosis of the pylorus is a very frequent occurrence. The greatest number of cancers of the stomach lead to it sooner or later. Early recognized cases are the most suitable for surgical aid. Wherever possible the tumor is resected; otherwise gastro-enterostomy is performed. An operation appears to me to be always indicated—when there exists ischochymia for some time and either a tumor felt or else the diagnosis of cancer of the pylorus can be made by other deductions—unless the tumor has assumed too extensive dimensions or the patient be too weak to stand an operation. Assuredly one can in many cases give great benefit for a more or less long period of time, and the sooner the more. Of the considerable number of cases of cancerous stenosis of the pylorus which I have seen during past five years, eight have been operated upon. Only in one the resection of the pylorus has been practised; in all others gastro-enterostomy has been performed by well-known surgeons of this city. One patient died during the first week after the operation. The remaining seven lived from two months to a year.

All these operated cases of cancerous stenosis had a more or less short period of illness (five months to one and a half year at the utmost) and showed considerable ischochymia. In all of them, with the exception of one, a tumor belonging to the stomach could be palpated. In two of the cases the position of the tumor could be accurately determined with the gastro-diaphane. From the result of the transillumination, it was concluded that the tumor in both cases lay principally in the small curvature of the stomach. Both cases had been operated on by Dr. F. Kammerer, at the German Hospital, and the diagnosis as to the position of tumor found correct. I may be permitted to append the drawings of these two cases as viewed with the aid of the gastro-diaphane (Figs. 3 and 4). All, with the exception of one, showed the absence of free HCl. The lactic acid test was present in six of the cases.

Of these cases I may be allowed to describe two, which presented some peculiarities deviating from the normal type of this disease. One of them resembled the cases of benign stenosis as regards the chemical condition of the stomach-contents; the second presented all the usual symptoms of a malignant stenosis; the presence of a tumor, however, could not be discovered.

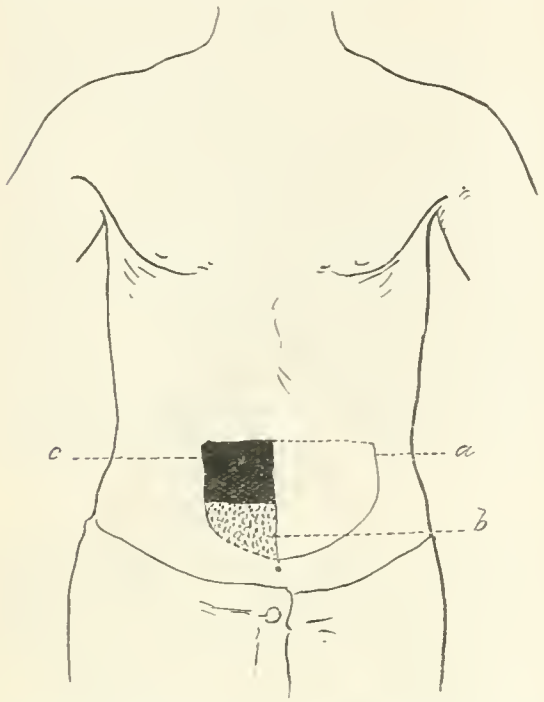

FIG. 3.—Result of Gastrodiaphany in patient K. N——, with Tumor in the Gastric Region. *a*, The transilluminated zone; *b*, the dotted spot slightly translucent on pressure; *c*, the black colored spot remains dark even on pressure.

Case I. March 9, 1894.—Oscar F——, thirty-two years of age, silk manufacturer, always robust and healthy, is suffering for the past six to seven months from digestive troubles which have been constantly increasing. They consist principally of pains, and for the last four months also of frequent spells of vomiting. Patient lost forty pounds in weight. Bowels not materially impaired. Poor appetite. Patient has never vomited any blood.

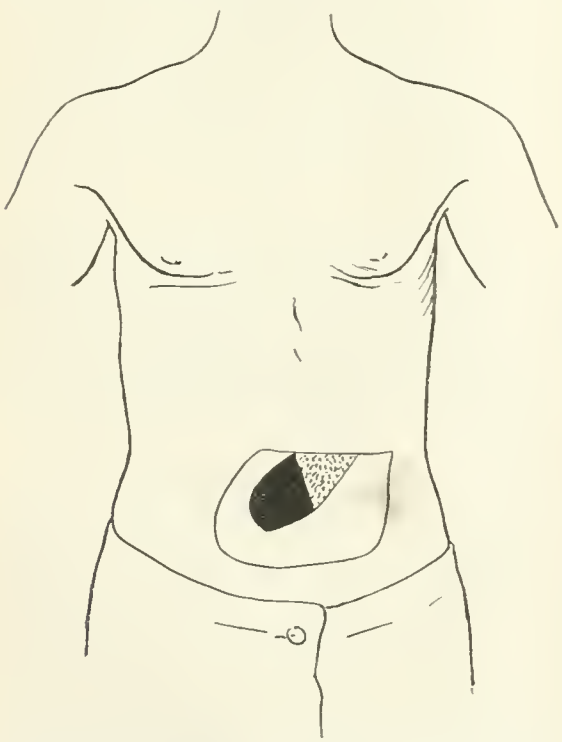

FIG. 4.—Result of Gastrodiaphany in patient M. R——, with Tumor in the Gastric Region. *a*, The transilluminated zone; *b*, the dotted spot slightly translucent on pressure; *c*, the black-colored spot remains dark even on pressure.

Present Condition: Patient looks thin and cachectic. Lips and cheeks are extremely pale. Chest organs intact. The palpation of the abdomen shows painfulness to pressure in the gastric region and an egg-sized tumor somewhat to the right and above the navel. This tumor is not especially painful to pressure, presents a smooth surface, and is easily movable. A splashing sound can be produced in the gastric region extending to two fingers' width above the symphysis.

March 9th.—At 6 o'clock P.M. Patient had taken a glassful of milk at 10 A.M. and did not have anything since. It was therefore eight hours after his last meal. Examination by means of the tube reveals the presence of two pints of chyme. The same shows a brownish color, contains small particles of casein, and various other foodstuffs. Chemically, HCl +; no lactic acid: acidity = 118; free HCl = 94.

Patient is instructed to take with his supper rice, milk, and crackers.

March 10th.—When fasting two pints of chyme are withdrawn from the stomach. The same presents a brownish color and contains food from previous days: rice, particles of bread, and casein. Microscopically: yeast cells, granules of starch, sarcina, bacteria, brown pigment.

Chemically: HCl +; no lactic acid; acidity = 112; peptone +; propeptone +; rennet +; erythrodextrin + little; achrodextrin + much.

March 12th.—The stomach is examined in the fasting condition and the same result obtained as on the 10th.

The high degree of ischochymia and the presence of a tumor in the pyloric region, pointed with certainty to a stenosis of the pylorus. It was questionable, however, whether the process was a benign or a malignant one. Whereas the chemical condition of the gastric contents pointed toward a benign stenosis, the large size of the tumor and the relatively short period of sickness (six to seven months) answered more to the history of a malignant growth.

After a consultation with Dr. F. Lange, we both were of the opinion that we had to deal here with a cancerous stenosis of the pylorus. This high degree of ischochymia appeared to necessitate surgical interference, which should consist in either resection of the pylorus or in gastro-enterostomy.

Patient was operated on by Dr. F. Lange, on March 16, 1894; the tumor was found (macroscopically) to be a cancer, and could not be resected on account of the numerous adhesions (principally with the colon). Gastro-enterostomy was established, and in about a month's time patient was able to leave the clinic and partake of a great variety of food. Soon, however, regurgitation, of bile into the stomach appeared, and a short while afterward "peristaltic restlessness"[1] of this organ also developed. Both conditions made patient feel very uneasy.

April 19th.—Patient was examined one hour after Ewald's test-breakfast. There was a considerable amount of bile in the gastric contents, which did not contain any food from the previous day. Chemically: HCl = 0; no lactic acid; acidity = 22.

Case II. August 2, 1894.—Albert D——, forty years of age, gardener, always robust and well, had a slight attack of indigestion in 1891, lasting only a short while. Later in 1892, patient had to work very hard and did not feel so well at times. He, however, attended regularly to his business. October, 1893, patient began to suffer from pains in his gastric region and from occasional vomiting spells. Patient could not eat any meat, as it revolted against him. Appetite ex-

[1] Remark. The peristaltic restlessness of the stomach in this case corresponded minutely to the picture given by Kussmaul in his celebrated paper on this affection.

tremely poor. Bowels constipated. Patient constantly became more emaciated, and lost thirty pounds in weight. During the last two months patient vomited almost every day.

Present Condition: Patient, of heavy build, looks emaciated. Tongue thickly furred. Chest organs do not reveal anything abnormal. Palpation of the abdomen reveals a round oblong body three inches in length, running horizontally about two fingers' width above the navel, which is thought to be the colon transversum. The epigastric region is tender to pressure but not painful. A tumor can nowhere be felt. There is a splashing sound in the gastric region extending to a hand's width below the navel. The urine contains neither sugar nor albumin, nor the coloring matters of bile. The examination of the stomach by means of a tube reveals the presence of old decomposed food.

August 3d.—One hour after Ewald's test-breakfast. The withdrawn gastric contents amount to 750 c.c., containing old foodstuffs (pieces of casein, particles of meat, bread, rice, etc.), and smelling very badly (fetid).

Chemically: HCl = 0; lactic acid + much; acidity = 40; rennet present only in traces.

Microscopically: Numerous bacteria and cocci, meat fibres, starchy granules.

August 5th.—When fasting, the stomach contains about 500 c.c. of chyme (therein considerable quantities of casein, rice, bread, and meat particles, spinach). Chemically, HCl = 0; lactic acid + much. Patient was treated with lavage regularly every other day in the fasting condition. There was always found ischochymia (food from previous days) with characteristic reaction for lactic acid, whereas free hydrochloric acid was constantly absent.

August 8th.—The stomach after a thorough lavage was transilluminated. The transilluminated zone began horizontally with the navel, extended downward to two fingers' width above the symphysis, and ran toward the right to a line lying slightly to the left of the navel (see Fig. 5).

Although no tumor could be discovered, the diagnosis of stenosis pylorie carcinomate was made for the following reasons: Short duration of illness, considerable ischochymia, the constant absence of free HCl, and the steady presence of lactic acid. Patient was sent to Dr. Willy Meyer for surgical interference.

August 23d.—Patient was operated upon by Dr. W. Meyer; when the abdominal cavity was opened, one saw the right lobe of the liver extending far downward and covering up the right side of the stomach. When the liver was lifted one noticed that the pylorus was replaced by a large cancerous tumor which was connected with the liver by numerous adhesions. The mesentery glands were infiltrated. The resection of the pylorus did not appear to be practicable. Gastro-enterostomy was then established by means of Murphy's button. Although patient was troubled with vomiting of large quantities of bile about a week after the operation, notwithstanding, this condition in a few days improved and the patient was then able to partake and retain larger quantities of food.

September 30th.—Patient had gained ten pounds since the operation and the examination of the stomach one hour after the test-breakfast showed that this organ was empty. Thus, there was no ischochymia; the contents had passed rather quicker than normally.

Although patient is still complaining of temporary attacks of pains, notwithstanding, his condition is undoubtedly better now than before the operation.

Conclusions.—If we now consider the points which were of value in diagnosticating a stenosis of the pylorus, the following may be given as a résumé.

a. Common Points.—Stenosis of the pylorus, benign as well as malignant, almost always presents symptoms of vomiting [1] and pains, is connected with a more or less considerable loss of weight, and objectively shows constant ischochymia. This condition is best recognized by the examination of the stomach by means of the tube when fasting. I usually instruct patient to have at his supper on the night preceding the examination, besides soup, meat, and bread, some rice, as this latter is very easily recognized and as a rule retained

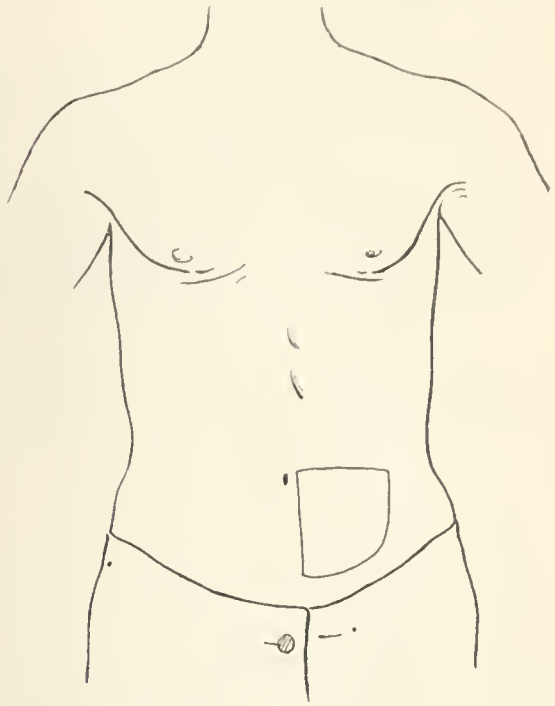

Fig. 5.—The Transillumination zone of the Stomach in patient Albert D——.

in the stomach when the pylorus is stenosed. For this examination the expression-method alone is not always sufficient. Wherever no chyme is withdrawn by this method, it is necessary to wash out the stomach. In these cases food is then continually found in the stomach.

Differential Diagnostic Points:

	Benign Stenosis of Pylorus.	Malignant Stenosis of Pylorus.
Duration of illness.	Long duration of illness (2 to 15 years).	Short duration of illness (5 months to 1½ year).
Run of the disease.	Long intervals without pain or periods of perfect euphoria.	No periods of perfect euphoria, but constant and gradual aggravation of the symptoms.
Tumor.	As a rule, absent.	Present in most cases.
Condition of Gastric Contents:		
Free HCl.	Present in the greatest majority of cases.	Nearly always absent.
Lactic acid.	Absent in the greatest majority of cases.	As a rule, present.
Acidity.	Always increased.	Fluctuates between 30 and 90.
Rennet.	Always present.	Varies.
Odor.	Unpleasant, disagreeable.	Very frequently fetid.

A long-lasting atony of the stomach may at times produce ischochymia; it is then, however, not constantly found and disappears soon after the regulation of diet and rational treatment. The same may be said of grave forms of chronic gastric catarrh. There also ischochymia is liable to develop under favorable conditions. The symptom, however, disappears after a few washings of the stomach. In this way I believe that these two conditions (atony of the stomach and

[1] Remark.—Vomiting may sometimes be absent, notwithstanding that ischochymia has already developed. I, at present, have under observation a patient with carcinoma pylori (with clearly palpable tumor), who has been ailing for the last six months. Patient had never vomited nor did he have much pain. His complaints merely refer to loss of appetite and obstinate constipation. The examination of the stomach in the fasting condition always reveals presence of chyme (coarse foodstuffs are principally found). Although patient, living on a more regulated diet, has gained six pounds within the last month, nevertheless the ischochymia remained unchanged.

chronic gastric catarrh) can be without difficulty discerned from a stenosis of the pylorus, and would give no cause whatever for mistakes.

As is clearly seen from the aforegoing, we are now enabled to diagnosticate a stenosis of the pylorus as soon as it causes ischochymia. Have we, therewith, reached the climax of the diagnostic art? I would like to answer this question with an emphatic "no." In many cases of benign stenosis of the pylorus there appear, at first, attacks of pain, unaccompanied by vomiting, which sometimes persist for years; probably, as yet, at that time no ischochymia exist—and still the disease is already much progressed. After the failure of many therapeutic means the patients find their last resort in morphine.

Among the morphinists there is undoubtedly a considerable number of patients with benign stenosis of the pylorus. If operated on, they would be also cured of their morphine disease. We should endeavor to look for methods which would enable us to recognize the malady already at this early stage.

An early diagnosis of malignant stenosis of the pylorus—before ischochymia has as yet developed or a palpable tumor appeared—would greatly increase the chances of an eventful radical operation and perfect recovery. Boas[1] has tried for this purpose to utilize the early appearance of lactic acid in cancer of the stomach. There are, however, on the one hand cases in which the constant appearance of lactic acid is observed and still no cancer exists (case Maria L——), on the other hand cases of cancer are met with without lactic acid (case Oscar F——). Notwithstanding, the lactic-acid test is certainly of great value.

As is evident from this paper the rational treatment of stenosis of the pylorus consists in establishing a wider outlet between the stomach and intestine. What shall we do in those cases where either surgical interference does not appear advisable, or patients refuse an operation? In these instances we shall apply the newer methods of treatment of the stomach. We shall advise small and frequent meals. In the benign stenosis the greater part of nourishment will consist of albuminates, whereas in cancer starchy food plays an important rôle. In both instances milk, kumyss, or matzoon, given in small quantities, are very suitable. In both instances lavage, applied in the fasting condition, appears to be very useful. After the lavage the spraying of the stomach with one to three per mille solution of nitrate of silver may be advantageously administered. Rectal alimentation will greatly aid the usual nutrition for a time, and rectal injections of water, which have been first recommended by Unverricht, will be of great benefit when thirst is present and the amount of secreted urine decreased.

In benign stenosis of the pylorus, the application of massage (ten minutes twice daily) to the gastric region can be warmly recommended. Likewise, the administration of alkalies in existing hyperacidity, and the application of the galvanic current when there are severe pains, may be profitably tried.

Cancerous stenosis of the pylorus hardly admits of any treatment. Condurango given when there is anorexia, and chloral hydrate (a tablespoonful of a three per cent. solution every two to three hours) when pains, as has been recommended by Ewald, are the most reliable and efficient medicaments.

107 East Sixty-fifth Street.

A Numerous Progeny.—A man died recently near Lebanon, Pa., at ninety-two years of age. He had been the father of twenty-two children, fifteen of whom survived him. There were besides, at the time of his death, one hundred and ten grandchildren and ninety-six great-grandchildren.

SOME NOTEWORTHY TOXIC EFFECTS OF THE ANTITOXIN TREATMENT IN DIPHTHERIA.

By A. SEIBERT, M.D.,

New York.

Inasmuch as Behring's treatment of diphtheria by the hypodermic injection of antitoxic blood-serum will no doubt be given an extended trial in the near future, it will be of value to carefully report any disturbances in the so-treated patients that are caused by the antitoxin.

The following case, while somewhat resembling those reported by Lublinski, of Berlin, and Scholz, of Hirschberg, in the *Deutsche Medicinische Wochenschrift*, November 8 and 15, 1894, presents additional features, which to my knowledge have so far not been published.

Lizzie J——, six and a half years of age, complained of illness, November 30th. On December 1st a fresh diphtheric exudate was found to cover the visible pharynx and the nostrils. Lymph-nodes swollen, temperature, 103.5° F.; considerable prostration. In the evening of the same day 10 c.c. of antitoxin (from the Pasteur Institute of this city) were injected, and the same quantity on the following morning. Irrigation (by a 1 to 20 watery solution of the liquor sodæ chlorinatæ) of the naso-pharynx made with a fountain-syringe every two hours, by night and day, and frequent gargling with a solution of iodine and carbolic acid, together with the antitoxin, practically cured the child in three days. An infant brother of the patient, aged eleven months, who had to remain in constant contact with his sister, was immunized by the injection of two c.c. of Aronson's serum.

The bacteriological report of the Health Department announced the presence of Loeffler bacilli.

To prevent any dangerous exercise, the patient was kept on her back in bed even after the disappearance of the exudate.

December 10th.—Nine days after injecting the antitoxin, and five days after apparent complete recovery, a rash appeared in the face and upon the extremities of the child, that in some places (face and neck) resembled measles and in others scarlatina. The skin was but slightly infiltrated, nowhere resembling urticaria. The color of the afflicted surfaces was dark red, showing a glossy, shiny appearance. The temperature had risen to 99.5° F., considerable itching, no pains. Appetite, normal. Normal urine. No treatment.

December 11th.—Erythema is disappearing.

December 12th.—Eruption has disappeared in the morning. Later in the day nausea, chill, headache, general malaise. Pains back of the head. On arrival I find patient with head drawn back, in high fever (104.9° F.); pulse, 140. Not somnolent. Posteriorly to the sterno-cleido-mastoid muscles large numbers of hard, swollen lymph-nodules are felt between the deeper cervical muscles. No succulent infiltration of the tissue surrounding the lymph-nodes. Each one can be distinctly felt. The posterior half of the neck appears swollen. Great tenderness, explaining opisthotonos position of head. Throat is positively clean. Tonsils small. No redness. Trace of albumin in urine. No casts. Treatment: Antipyrin, four grains in watery solution, given six times in twenty-four hours per rectum. Much relief at night. Erythema barely visible in faintly bluish spots on extremities.

December 13th.—Infiltration of cervical lymph-nodes subsiding. No swelling of lymph-nodes in groin, axilla, or other parts. Temperature, 101° F. No appetite. Trace of albumin. Tenderness of neck almost gone by evening.

December 14th.—During the night, 3 A.M., violent nausea and vomiting, chill, pains all over body, but especially in joints. At 9.15 A.M., I find temperature 104.8° F., pulse 140, a new eruption over the face, in-

jection of both conjunctivæ, marked œdema and redness of upper eyelids. Face, neck, and extremities covered with large and small blotches. Trunk shows but few smaller spots. Joints of wrists, knees, elbows, and ankles are tender and slightly swollen, but not reddened as in acute rheumatism. The left hip-joint is very tender. The infiltration of cervical lymph-nodes has entirely disappeared, and the head can be moved in all directions. Trace of albumin. Some few casts. Anorexia. No headache. Treatment: Six grains of salicylic soda in watery solution, given every two hours per rectum. Temperature, 103° F., 5 P.M.

December 15th.—Pains in joints much better. Temperature, 102° F.; pulse, 116. Erythema less marked. Has disappeared from conjunctivæ. Upper eyelids still swollen and red. A few isolated lymph-nodes can be felt at back of neck. No tenderness. Pains now back of the knee-joints and more marked along the muscles leading from the affected joints. Trace of albumin. Few casts. 9 P.M., temperature, 104.2° F.; pulse, 120.

December 16th.—Joints entirely free. Muscles tender. Erythema disappearing. Still marked in face. Anorexia. Temperature, 101° F., A.M. Heart normal. Very thirsty. Had a restless night. 9 P.M.: Erythema has completely disappeared. Pain only in tendons, back of both knee-joints. Temperature, 100.5° F.; pulse, 96. Some appetite. Trace of albumin.

Remarks.—That the symptoms recorded here were due to the antitoxin alone is evident for the following reasons: 1. No local disturbance appeared at the points of injection, thereby excluding the possibility of an unclean syringe. 2. The erythema appeared exactly ten days after the injection of the antitoxin, exactly the time given in two cases of Scholz (*l. c.*), and the case of Lublinski (*l. c.*). 3. Swelling and pains in joints, and tenderness of muscles and tendons (the latter back of the knee-joints), were well marked in all four cases. 4. The affection persisted in all cases for four to seven days.

Our case differs from those of Scholz and Lublinski in so far that the patients of Scholz (his own children) presented no rise of temperature; the one of Lublinski showing temperature of 101° to 103.4° F., and but one rise to 104.5° F.; while the fever in our case was but slight during the first eruption (99.5° F.), but showed marked tendency to go above 104° F. during four successive days.

In our case we saw two distinct eruptions. On the disappearance of the first a sudden infiltration of the posterior cervical lymph-nodes appeared, together with a marked chill and high fever. This phenomenon passing away, a new chill and rise of temperature initiated another eruption of the characteristic erythema, together with articular affection and muscular pains.

The difference between the four cases appears to allow an explanation, best seen by tabulation.

1. Scholz: Boy, aged ten. 600 antitoxin units. Behring. Erythema, articular and muscular pain. No fever.
2. Scholz: Girl, 600 antitoxin units. Behring. Erythema, articular and muscular pain. No fever.
3. Lublinski: Girl, aged eight. 1,200 antitoxin units. 10 c.c. Erythema, articular pain. 101° to 104.5° F.
4. Seibert: Girl, aged six and a half years. 20 c.c. Pasteur Institute. Two eruptions of erythema; lymph-node infiltration; two chills; temperature, 104.9 F.; joint and muscular affection.[1]

In the first two cases but 10 c.c. of Behring's weakest serum was injected, hence erythema, articular and muscular affection appeared without a rise of temperature.

In the third case the double quantity was used within twenty-four hours, hence these symptoms came on with fever, ranging from 101° to 104.5° F.

[1] Since the above was written, I have found two more cases, by Mendel and Asch (Berl. klin. Wochensch., November 26, and December 17, 1894), two others by Cuyrine (Deutsch. Med. Woch., November 29, 2834), and a fifth by Porteaux (New York Medical Journal, January 12, 1895), in all, nine cases.

In our case 20 c.c. (from Pasteur Institute) were injected within twelve hours, hence the two eruptions, the lymph-node infiltration, the joint and muscular affection, and the high temperature. The first two cases recovered in four, the third in five, and the last in seven days.

Although we are not informed as to the relative strength of the antitoxin from the Pasteur Institute, it appears as though the 20 c.c. injected were much more powerful in their after-effects than the weakest serum of Behring (No. 1).

The albuminuria seen in our case I am inclined to attribute to renal stasis.

In the small number (fourteen) of other cases of diphtheria I have treated with antitoxin, no after-effects appeared. The wonderful similarity as to the time of their appearance as well as to their location, shows that these after-effects are due to the antitoxin itself, and not to any difference in its production.

137 East Nineteenth Street.

EPICEREBRAL HEMORRHAGES IN PARESIS, WITH ILLUSTRATIONS.

By L. PIERCE CLARK, M.D.,

Middletown, Conn.

Within the past few years the post-mortem appearances of the brain in general paresis have been carefully observed, described, and recorded. Nevertheless, it seems to me that many of the descriptions of these hemorrhages found on the brain cortex and in the membranes, however clearly described, cannot but fail to give an inferior mental picture to that of photographs taken at time of autopsy. Therefore two photos are given showing these post-mortem appearances in a typical case of general paresis. Attention is called especially to these hemorrhages which were found on the surface of the brain and beneath the pia, or so-called epicerebral hemorrhage. These should not be confounded with the subdural hemorrhage or arachnoid cysts so often found in general paresis; as these were also present in the brain and came away with the dura. The larger and more pronounced subdural hemorrhages were not in apposition with these in the epicerebral space. For obvious reasons these were not incorporated in these photos.

The pial membrane was carefully cleaned over these spots before the pictures were taken, in order that none of the sero-sanguineous exudate in the meshes of the arachnoid should appear in the photo. The pia and underlying cortical gray substance were examined to determine the origin of these hemorrhages. The membrane was so adherent over the brain that it was impossible to remove it without destroying a large quantity of the gray matter. Over the immediate areas of hemorrhage the pia was less tenacious and adherent, which was probably explainable on the ground that the steady pressure of the hemorrhage had elevated the pia and caused a degeneration of the branching connective-tissue cells commonly found extending, spider-like, from the first layers of the brain to the overlying pial covering.

Under the microscope the vessels of the pia were engorged and tortuous; the tissue either side of the blood-vessels was closely infiltrated with leucocytes, as in other parts of the brain's pia. It was thought probable that a ruptured or eroded vessel might be found from which the blood effusion escaped, but diligent search failed to disclose any.

The cortical areas after the removal of the pia still retained the rusty appearance, or "rusty spots," as Bevan Lewis has so aptly named them. The large, rusty spot on the tempero-sphenoidal lobe, displayed in Fig. 2, not only shows the area and color, but also softening and actual cortical disintegration in the sum-

mit of the gyri. Frozen sections of two or three of these areas, stained by osmic acid and aniline blue-black, presented all the degenerative characteristics of tissue taken from other parts of the cortex. A few blood-stains and crystals were found in these sections. With the same end in view as in examining the pia the blood-vessels were searched for a solution of continuity, but it proved alike unsuccessful. It seems more probable that instead of rupture of the blood-vessels of both the pia and gray matter, the arterioles had become so thin and degenerate through loss of their normal stout tunics, both by hyperæmia and secondary fatty change, that it became impossible for them to prevent free diapedesis of their contents into the perivascular space and surrounding brain tissue. The rest of the cell element of the cortex showed the degeneration of tissue commonly found in general paresis—proliferation of the lymph connective system, erosions of dendrons, etc.

FIG. 1.—Epicerebral Hemorrhages.

As to the site of these hemorrhages, they are recorded as occurring in the temporal, parietal, and occipital lobes, occasionally at the base, and but rarely in the cerebellar fossa. It will be noticed that in Fig. 1 the three hemorrhages which are most prominent are superior parietal anteriorly and posteriorly, and a well-marked spot occurring on the superior surface of the cerebellum. In Fig. 2—picture of the base—these spots were less distinct, probably on account of their being less severe and more recent than the others. The remains of these hemorrhages were particularly noticeable at the base and tip of the frontal lobes, and were also quite prominent about the olfactory lobes. Over almost the whole of these latter two named areas, even before the pia was removed, the peculiar moth-eaten appearance of the cortex was plainly visible. In the dura covering the paracentral lobule two small, bony plaques were found, apparently ossification of the Pacchionian bodies.

FIG. 2.—General paresis. *a*, Remains of epicerebal hemorrhage and cortical softening; *b*, area showing moth-eaten appearance of brain-cortex.

For those wishing to make some comparison between the symptoms and the pathological conditions presented in this case, Dr. Keniston has kindly furnished me a short abstract of the patient's history.

F. G——, forty-seven years of age; widower; a painter by trade. On admission to the hospital he presented the characteristic paretic symptoms, somatic and psychical. Tremor of tongue, lips, and facial muscles were well marked, accompanied by entertaining the delusions of great wealth and well-being. His disease was thought to have extended over a period of about three years. During the latter part of this time the patient had done many foolish acts, and committed two or three small crimes, for which he had served a few months in the county jails. He had led a very wild and dissolute life, and on arrival at the hospital presented some physical evidences that he had contracted syphilis, but this could not be verified from patient's knowledge.

Four months after admission it was impossible for the patient to walk or get about in any manner, through loss of motor power and inco-ordination. Speech had become so indistinct as to be unintelligible, and deglutition was much impaired. For the past two months he had forgotten his delusion of wealth, and retained only his happy, helpless, and demented appearance. The trophic neuroses were manifest in his case by the large number of bed-sores present in the last few months of his illness. He died September 14, 1894.

During the entire course of the disease he had no convulsive seizures, and consequently the relation of the paretic convulsions to that of the hemorrhages does not seem to be borne out in this case, *i.e.*, the larger and more extensive hemorrhages are found in those paretics who have had many convulsions.

Not a Pleasant Man to Live with.—M. Octave Feuillet, from all accounts, must have been a hard man to live with. Mme. Feuillet, who ought to know, declares that he was a victim to his nerves. A strange voice, one he was unaccustomed to, in the house, made him wild. When he was ailing, mattresses had to be piled up against his doors, so as to keep out the ordinary noises. When in the country the crowing of cocks, the cackling of hens, the neighing of horses, made him frantic. For a man of poetical temperament the twitter of swallows, the chirping of sparrows, caused him agony. By steady pistol practice, says his wife, he exterminated all the owls in a country garden where he was living.

Russification of the University of Dorpat.—An official notification has been sent to the Council of the University of Dorpat (henceforth to be known as Yurieff) that from the beginning of 1895 all the professors in the University, with the exception of those of the Theological Faculty, must give their lectures in the Russian language.

Progress of Medical Science.

The Treatment of High Arterial Pressure.—The fact that high arterial tension is a condition which requires medicinal interference has become more and more recognized as we have employed the nitrites with constantly increasing frequency. Indeed, it is probable that many physicians of the present day who employ nitro-glycerine or other nitrites as cardiac stimulants, in reality get the good results obtained solely through the decrease in the arterial tension, which results in the easier action of the heart (*The Therapeutic Gazette*). In other words, the improved action of the heart after nitro-glycerine has been given is not due to the fact that it has acted as a cardiac stimulant, but rather that by decreasing the work of the heart that organ is able to perform its function more satisfactorily. A mistake is frequently made by the careless physician when called to a case in which the heart is evidently failing. Signs of cardiac exhaustion and of dilatation divert his attention from the high arterial pressure, and, as a result, he jumps to the conclusion that the failure of the heart is due to an actual lack of strength in that viscus, when in reality its failure is produced not because it is weaker than normal, but because the arterial tension is so great that even with compensatory hypertrophy it is almost impossible for it to force the blood through the contracted blood-vessels. Too frequently, under these circumstances the physician attempts, by the administration of digitalis, strophanthus, or other cardiac stimulants, to so increase the power of the heart that it will overcome the tremendous resistance to its normal action. Sometimes, under the effect of this stimulation, temporary improvement does take place, but the rational therapeutics of such a case demands that the pressure shall be taken away, and the heart not only allowed to rest, but also quieted, in some cases, by drugs which, if not direct cardiac depressants, certainly act as sedatives to this organ. It would seem that in many cases of high arterial tension the spasm of the vessels is due more to a condition of hyper-excitability of the vasomotor system than to any direct pathological change in the blood-vessel walls. For this reason the administration of nervous sedatives is often of advantage, either with or without the use of nitro-glycerine. A prescription such as follows may be employed in some of these cases with advantage, particularly as it aids in relieving the restlessness of the patient, who may rebel against being confined or deprived of exercise:

℞. Chloral ..... ʒ ij.
Bromide of sodium ..... ʒ ij.
Syrup of lactucarium ..... f ʒ j.
Water, q. s. ad ..... f ʒ iij.

M. Sig.: A teaspoonful should be taken in a little water every four hours, or not less than three times a day.

In many cases, as is well known, the use of nitro-glycerine, while indicated by the condition of arterial tension, is contra-indicated by reason of the headache which it produces in susceptible persons, and in such instances this prescription may also be given with advantage.

Is Biliary Lithiasis of Microbic Origin?—The Paris correspondent of the *Medical Press* writes that this question was discussed in a paper by MM. A. Gilbert and S. A. Dominici at a meeting of the Societe de Biologie. Since M. Galippe in 1886 showed the presence of micro-organisms in biliary calculi the question has remained in abeyance until taken up by the authors. They have examined calculi from six cases. In two cases in which the lithiasis was of recent date they were able to demonstrate by coloration and culture the presence of organisms in the centre of the calculi. In two cases in which the lithiasis was of ancient date examination yielded only negative results. In one case in which the lithiasis was of equally ancient date, cultures yielded only negative results, but in colored sections microbic forms were discoverable. In another case, where old and recent calculi existed together, the first gave negative results, but the second, on the contrary, gave positive results both in examination of sections and by cultures. Where culture succeeded, the organisms which developed belonged to the coli-bacillary species. These results are explainable by two hypotheses. First, it may be assumed that the formation of calculi has preceded their invasion by bacteria, and this hypothesis is the more tenable from the fact that in cases where calculi contained the coli-bacillus the bile was infected with the same germ. On the other hand, it may be assumed that infection by the coli-bacillus has formed the initial stage from which the lithiasis has proceeded. The authors adopt the second of these hypotheses. They have tried to verify the theory of the microbic origin of biliary lithiasis experimentally, and with this object they injected into the gall-bladder of three dogs cultures of Eberh's bacillus and into the gall-bladder of one dog Escherich's bacillus. Of the animals inoculated with the first-named bacillus the first succumbed at the end of a month with a suppurating cholecystitis and double pneumonia. The second died in three months without lesion of the gall-bladder, and with a magnificent (*sic*) vegetating endocarditis of the mitral and tricuspid valves. The third was killed after three months, as also the animal inoculated with the coli-bacillus, but nothing was discovered after death. The experiments under different conditions are to be pursued by the authors.

Persistent Recurrences of Influenza.—Dr. Thibaudet remarks that immunity from influenza, supposing that it exists at all, is of short duration. From a symptomatic point of view nothing occurs in the interval between the different attacks. The apyretic patient recovers in the usual way, more or less exhausted and asthenic, according to the mode of reaction peculiar to each person, and, above all, according to the presence or absence of anterior morbid conditions. Suddenly the disease returns; fever reappears, and at the same time the characteristic pains in the head and limbs, coryza, coughing, laryngo-tracheo-bronchitis in the thoracic form, vomiting and diarrhœa in the gastro-intestinal form, and prostration and extreme lassitude in all forms appear. Generally the symptoms which predominated the first time appear again, but this is not always the case. Aside from complications, the duration of these new attacks is not longer or shorter than that of the first attack. Those which occur from six months to two years or more after the first seizure are not doubtful, and all physicians who practise in regions where influenza is endemic have observed many examples. It appears, then, that, far from conferring immunity, the first attack of influenza often predisposes the patient to a return of the disease.

Many physicians think that the disease is due to the swarms of common microbes living in the organism, especially on the skin and in the mouth, and that under certain influences, especially meteorological, the virulence of these germs increases enormously, the danger of contagion becomes greater, and an epidemic is the result. After a careful study of this question, and after experience with this disease, Dr. Thibaudet thinks the following conclusions may be drawn: 1. That during a period of from twenty days to four months influenza may attack the same organism from two to four times, with more or less prolonged intervals of complete apyrexia. 2. That these repeated attacks should be attributed to a series of autochthonous reinfections in a soil especially favorable to them. The greater virulence of the pathogenic germ is commensurate with the greater contagiousness.—*New York Medical Journal.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, January 19, 1895.

THE CAUSATION OF CANCER.

THERE is a growing belief, or rather impression, in the mind of the profession that cancer may be found to belong to the group of infectious diseases; that its growth depends upon the presence of an animal microparasite, and reports are constantly being published of experiments made with a view to settle this point. So far, however, nothing definite has been accomplished. Dr. D'Arcy Power has recently completed a very elaborate experiment, which we find described in a reprint from the *British Medical Journal* of September 22, 1894. The animals experimented upon were very old or very young white rats, which may be assumed to be more vulnerable than adult animals which run wild. These animals were kept in low wire cages resting on soil taken from those districts in England in which cancer most prevails. This soil was thoroughly mixed with fresh cancer tissue, and kept moist with water in which cancer tissue had been ground and pulped. The rats were from time to time sprayed with a thin cancer pulp, and their mucous membranes were kept in a state of chronic irritation so that the protozoon, if any existed, might find a suitable medium for its reception and a favorable soil for its growth. The rats, six in all, lived in this way for about eleven months. Two died, one from cold, the other from intestinal perforation by a tape-worm, and four were killed. A careful examination was made in each case, but in none could a trace of cancer be found anywhere either by the naked eye or under the microscope.

At the Congress of the French Surgical Association, held at Lyons last autumn, the "Etiology and Pathogenesis of Cancer" was one of the set subjects for discussion. Four of the members took part in the debate, one of whom, M. Guelliot, upheld the parasitic theory, bringing, however, no facts of any importance to the support of his thesis. M. Bard, of Lyons, believed that there is but one mode of origin of all malignant tumors, whatever may be their structure. For each tissue there is a special form of cancer, the origin of which is a single too vigorous young cell, whose power of proliferation is exaggerated and unlimited. This cell is large, juicy, and provided with a large nucleus. There is nothing about it in the nature of a degeneration, the latter being a disease of the tumor and not a state proper to it. The cancer-cell preserves its own evolutionary type, even in secondary tumors, the grouping of the cells in the metastatic growth being in plaques, if the original cell is pure pavement epithelium, or in tubes, if the primal cell is from cylindrical epithelium. According to M. Bard, therefore, cancer is the result of a freak. A cell endowed with unusual proliferative powers is produced, and being freed from the "inductive influence" which the organism as a whole exerts upon each individual cell, it exercises these powers freely and transmits them to its numerous descendants. This disturbance of inductive influence is hereditary, but is favored by external causes, such as ulceration, traumatism, or age. The theory is pleasing enough, but M. Bard brings forward no facts in support of it.

In the meanwhile, in spite of the negative results of most experiments, and the doubtful results of a few others, and in spite of arguments against it, the feeling that cancer must be a specific disease, arising from the presence of a protozoon, seems to be gradually spreading. The search for the protozoon will doubtless continue, but he would indeed be rash who would prophesy as to its outcome.

THE THREATENED REVIVAL OF THE WHIPPING-POST.

AT the meeting of the Public Health Section of the Academy of Medicine last week the subject for discussion was the whipping-post. There was not the popular interest manifested that had been anticipated, only a small audience being present. Nevertheless the discussion *pro* and *con* was animated. It was held on the one hand that whipping offenders convicted of crimes against the person would be highly efficacious as a deterrent of similar crimes; and on the other, that, since crimes of this character are usually committed under the influence of passion or during periods of mental irresponsibility—alcoholic or otherwise—the fear of punishment could exert but little deterrent influence. The thought was also advanced that to apply corporal punishment only in the class of cases suggested (*i.e.*, where the crime involved the infliction of pain by the criminal), savored very closely of the old punitive methods, and little of the modern reformative idea.

The discussion centred about a proposed bill, which Mr. Gerry, of the Society for Prevention of Cruelty to Children has drafted for introduction into the Legislature, providing that felonies against the person may be punished, at the discretion of the judge who pronounces sentence, by castigation in addition to imprisonment. Mr. Gerry holds that imprisonment, even for a term of years, is but little deterrent upon the class of offenders who commit these crimes. He thinks that the only thing these persons fear is pain, and that a flogging will accomplish far more than imprisonment, though the former is not to supplant it or to supplement the latter.

It can hardly be said that this argument carries conviction with it. One cannot easily conceive the mental complexion of a man who would prefer years of imprisonment to a single flogging in private (it being explicitly provided in the proposed bill that only a physician and the prison warden shall be present when the flogging is given). When we recall further that the criminals in question are notoriously anæsthetic, paying little heed to physical injuries that would be exquisitely

painful to ordinary persons, and constantly receiving such injuries in bar-room brawls and street fights, it becomes still more open to doubt whether the prospect of receiving "forty lashes at most," in private, will deter one of them who, in a moment of passion, or while intoxicated, is tempted to beat his wife or to commit rape or sodomy (these being the crimes chiefly had in mind by the advocates of the proposed measure).

It seems probable, therefore, that most physicians will be disposed to agree with those speakers at the meeting in question who counselled great caution in the matter, urging that we should make very sure indeed that the proposed measure is calculated to either reform the criminal or deter the would-be criminal, before countenancing its adoption. There is certainly an element of plausibility in the suggestion made by one of the speakers, that if we are to have the whipping-post at all, it should be used to correct minor delinquencies rather than major crimes; the idea being to endeavor to shame the misdemeanant from the course he has entered on; to avoid the necessity of sending him to that most potent nursery for crime, the county jail; and to exercise a deterrent influence upon other wayward and wavering mortals. It would certainly seem as if this use of the whipping-post, if any, would accomplish the best results. Advanced penologists are pretty generally agreed that for major crimes the indeterminate sentence, with its reformative possibilities, must be the hope of the future in dealing with the criminal. The use of corrective flogging may possibly enter into the reformative system with benefit, as at Elmira; but this is a very different thing from inflicting pain upon a criminal as a retributive measure; *i.e.*, causing him pain because his crime has involved the infliction of pain upon his victim. We should regret to think that such a vengeful application of corporal punishment could meet the approval of the medical profession. And we very much doubt whether any application whatever of corporal punishment would meet their sanction.

THE EFFECTS OF INTENSE COLD UPON THE MIND.

Extreme cold, as is well known, exerts a benumbing influence upon the mental faculties. Almost everyone who has been exposed, for a longer or shorter period, to a very low temperature has noted a diminution in will-power, and often a temporary weakening of the memory. Perhaps the largest scale upon which this action has ever been studied was during the retreat of the French from Moscow. The troops suffered extremely from hunger, fatigue, and cold—from the latter perhaps most of all. A German physician who accompanied a detachment of his countrymen, has left an interesting account of their trials during this retreat. From an abstract of this paper by Dr. Rose, in the *New Yorker Medicinische Monatschrift*, we find that of the earliest symptoms referable to the cold was a loss of memory. This was noted in the strong as well as those who were already suffering from the effects of the hardships to which they had been exposed. With the first appearance of a moderately low temperature (about five degrees above zero Fahrenheit), many of the soldiers were found to have forgotten the names of the most ordinary things about them, as well as those of the articles of food for the want of which they were perishing. Many forgot their own names and those of their comrades. Others showed more pronounced symptoms of mental disturbance, and not a few became incurably insane, the type of their insanity resembling very closely senile dementia. The cold was probably not alone responsible for these effects, for a zero temperature is rather stimulating than paralyzing in its action upon the well-fed and the healthy. These men were half-starved, poorly clad, worn out with long marching, many already weakened by dysentery and other diseases, and all mentally depressed, as an army in defeat always is. It needed, therefore, no very unusual degree of cold to produce the psychic effects observed under other circumstances only as a consequence of exposure to an extreme low temperature.

THE GRIP.

There seems to be no doubt that "grip" is prevailing very extensively throughout this city and its suburbs. It usually takes the form of a rather sharp attack of bronchitis or coryza, with pains in the limbs and back. There is a slight rise in temperature of one to three degrees. The patient is usually quite prostrated, and feels depressed and weak for several days or longer. The disease, so far as we can learn, is much milder than it was when it first visited us in 1891. Occasionally, however, pneumonia develops with serious results. During the first week of this year there were 7 deaths from grip; during the first week of 1894 there were 13; of 1893, 3; of 1892, 89; of 1891, 19.

The grip, as it now affects the population, runs a course in most cases like an ordinary cold, and is distinguished only by the pains and prostration that accompany it, and by the greater evidence of contagion. Once in a family it is very likely to attack many or all of its members.

Much good advice has been given as regards prophylaxis; but no specific is known. The avoidance of exposure, of excessive fatigue, and, especially, of close association with those who have the disorder, is to be recommended. Undoubtedly, the use of quinine and iron and of throat gargles, and attention to the diet, are helpful. Doctors are apparently very susceptible to it, and this is due, no doubt, to their frequent association with cases of the disease, and to the fatigues and exposure incident to their calling. Medical men are not as wise in caring for themselves as they are in looking out for others.

The Charcot Monument.—The subscriptions toward the erection of a monument to Charcot, received directly by the Committee, now amount to about twenty-five thousand francs (£1,000). Of this a large part has been contributed by foreign admirers of the great neurologist. In addition to this sum the *Progrès Médical* has collected about ten thousand francs for the same purpose.

News of the Week.

Dr. Parker Widney died of pulmonary phthisis on December 23, 1894, in Piqua, O. He was a graduate of the University Medical College in this city in the spring of 1893, and gave promise of a brilliant career. But his health failed, and despite a sojourn in Southern California he was obliged to abandon the hope of practice, and returned to the home of his parents, where he died.

A Severe Epidemic of Diphtheria is prevailing in the town of Wesley, Mass., near Northfield. Wesley is a town of about three hundred inhabitants, mostly Bohemians. Already there have been over fifty deaths.

The Third International Dermatological Congress will not be held this year as was proposed. The time of meeting has been postponed because the British Medical Association meets in London this summer, and it was feared by the Executive Council of the Congress that the autonomy and international character of the Congress would be imperilled by holding its meeting at the same time and place; as well as that the necessarily divided interests of the British dermatologists would prevent that full exercise of hospitality to their foreign visitors that they so much desire to extend. As the next meeting of the International Medical Congress will be held in Moscow, in 1896, it is possible that the Dermatological Congress may not be held until 1897.

The Late Dr. John W. Pinkham.—The Orange Mountain Medical Society of New Jersey, learns with deep regret of the death of Dr. John W. Pinkham. Dr. Pinkham was born in Gardiner, Me., was a graduate of Haverford College, Pa., and of Bellevue Medical College, New York. He commenced the practice of medicine in Montclair, N. J., in 1867, and was so engaged until 1890, when by reason of ill-health he was compelled to give up active work. He died December 7, 1894, of apoplexy. He was the author of numerous articles on hygiene and preventive medicine. Dr. Pinkham was a charter member of the Orange Mountain Medical Society, and continued an active and earnest worker until his resignation—on account of ill-health—in 1892. The Society greatly regretted his loss and elected him an honorary member. His work on intubation of the larynx will long be remembered by his associates. It is the wish of this Society to express its deep sorrow for his death, and show its earnest sympathy for the bereavement which has befallen his family.

Mefford Runyon,

William H. White,
Committee.

Corporal Punishment for Certain Forms of Crime.—Dr. Andrew F. Curier, in a paper before the New York Academy of Medicine, January 9th, strenuously advocated corporal punishment for wife-beating and other forms of personal brutality, and urged that a suitable law for that purpose be enacted. None of the usual punishments inflicted appealed to the brutal natures of the criminal, and the infliction of pain was apparently the only remedy. The object of such castigations being deterrent and reformatory, the only spectators necessary were the castigator and a physician. The efficacy of flogging in Delaware was also referred to. A communication from Dr. W. C. Wey, of Elmira, was read, referring to the beneficial results of such punishment in the Elmira Reformatory. The discussion was opened by Elbridge T. Gerry, Esq., who warmly seconded the proposal, and who advocated the infliction of such punishment not only upon woman-beaters, but those guilty of sodomy, assaults on children, and like crimes against the person. He also read the text of a bill to be presented to the Legislature. The Rev. Dr. B. F. De Costa and Dr. E. H. Grandin also favored the measure, the latter advocating emasculation for lustful crimes.

Hospitals and Fire-escapes.—A bill has been introduced into the New York Legislature providing that hospital buildings over two stories high shall have iron stairways constructed on the outside of the buildings to be used in case of fire.

The Sixteenth Congress of Balneology will take place in Berlin on March 7, 1895, and four following days, under the presidency of Professor Oscar Liebreich.

Dr. Bertillon, the inventor of the anthropometrical system, asserts that he has discovered a new process for identifying handwriting. It is based on the measurement of beatings of the pulse, which are said to have in everybody a different and characteristic effect on handwriting. The inventor enlarged specimens by photography till the letters were a foot high, and then the characteristic marks were seen.

The New York City Health Board will appoint six new assistants in the Bacteriological Department, at an expense of $12,000.

New York State Board of Health.—Governor Morton has nominated for this board Daniel Lewis, M.D., of New York; S. Case Jones, M.D., of Rochester; and Owen Cassidy, of Havana.

Proposed Coroner Legislation.—A bill has been introduced into the New York Legislature providing for one coroner in New York when the terms of those now in office expire. He is to be a judicial officer solely, to sit without a jury, at a salary of $10,000. The duties of investigation, etc., are to be performed by the Coroner's physicians, of whom there will be six instead of four.

A Bill is Pending before the Alabama Legislature, compelling patent medicines to have the formula printed on the bottle. A strong lobby is working against it.

Hypnotism and Its Effects.—The town of New Regel, O., is a religious community. A travelling hypnotizer recently hypnotized a large number of the citizens. For several days after the town was subject to epidemic insanity evident in hypnotic performances, which rival those of witchcraft times. In a murder case on trial at Columbus, O., the prosecution claims that the insane performances of the defendant in the

court were due to his having been hypnotized for the purpose. It is said to be established that a physician practised hypnotism on the alleged murderer.

An Aged Medical Bicycler.—Dr. Westbrook Farrier, of Biddeford, Me., is, so the story runs, in active practice at the age of ninety-eight, and is in the habit of visiting his patients regularly on a bicycle. He attributes his exceptional vigor at this advanced age to the use of wintergreen tea, of which he is an ardent advocate.

The Chicago College of Physicians and Surgeons is about to be absorbed by the University of Illinois. The University trustees have recommended the purchase of the college for an amount not to exceed $160,000.

Dr. J. E. Lee, of New Haven, Conn., recently acquitted of murder in an alleged case of malpractice, must stand a new trial under a recently passed act, which revives in this State what Macaulay calls "the most absurd and odious proceeding known to the old English statute law," the appeal of murder. The law is clearly unconstitutional under Amendment VI. of the United States Constitution.—*Medical Standard.*

Death from Chloroform.—Dr. F. J. Hodges, of Anderson, Ind., recently gave a woman, suffering from a uterine tumor, chloroform. It was then found the tumor did not permit of operative treatment. The patient died soon after regaining consciousness.

The Professorship of Physic at Oxford has been held for thirty-six years by Sir Henry Acland, who has just resigned. His place is filled by the appointment of Professor Burdon-Sanderson. It is proposed to raise a testimonial fund of $50,000 for the endowment of the Sarah Acland Home for Nurses.

The City Board of Health.—It is announced that Dr. Charles S. Benedict has been appointed to succeed Dr. Doty as chief of the Bureau of Contagious Diseases.

Professor William Osler.—The announcement that Dr. William Osler, of the Johns Hopkins University, Baltimore, has been called to the presidency of McGill University is not true.

A State Examination in Georgia.—The new law providing for a State board of medical examiners (really, three boards—regular, homœopathic, and eclectic), went into effect on January 1st.

The Priority of the Discovery of Antitoxin.—Professor Jaime Ferran, of Barcelona, has called the attention of the editors of the *Deutsche medicinische Wochenschrift* to a paper by him entitled "Nota sobre la vacunacion contra el envenenamiento difterico agudo experimental," bearing date April, 1890, in which a safe and practical method of immunizing animals against fatal doses of the diphtheria poison, successfully employed by him, is described. On the basis of this publication, which appeared eight months before Professor Karl Fraenkel's communication on the same subject, Dr. Ferran claims the priority of the discovery. The Spanish bacteriologist's claim, together with the *pièces justificatives*, having been submitted to Professor Karl Fraenkel, has been frankly acknowledged by him to be well founded. He says (in a letter published in the *Deutsche medicinische Wochenschrift* of December 27th) that after reading Dr. Ferran's paper he has been able to convince himself that the Spanish worker had in fact, in April, 1890, reported the result of prolonged experiments on the immunization of guinea-pigs against infection with diphtheria bacilli, adding, "there can therefore be no doubt that in this question decisive priority belongs to him." Professor V. Babes, of Buda-Pesth, also lodges a claim on his own behalf. He points out, in the same number of the *Deutsche medicinische Wochenschrift*, that, whereas the first communication by Drs. Behring and Kitasato on the immunizing power of the blood-serum of artificially immunized animals in the case of tetanus, was published in 1890, in the *Deutsche medicinische Wochenschrift*, No. 49, 1890, he, in co-operation with Dr. Lepp, had established the same principle as regards "a not less important infective disease" (hydrophobia) in 1889, in a paper published in the *Annales de l'Institut Pasteur*, July, 1889. Professor Babes, however, admits that to Behring belongs the credit of applying the principle to diphtheria. All he claims for himself is that he took a definite part in laying the foundation-stone of the great and solid structure which Behring and his fellow-workers have raised.

The Discussion on the Value of the Diphtheria Antitoxin at the Berlin Medical Society, was concluded at the third session of the society. Dr. Schiemmann warned general practitioners against employing the antitoxin, which he said should be left to the hospitals for the present. Professor O. Liebreich, director of the Pharmacological Institute of the University, criticised the published serum statistics. He said that the Berlin hospitals had always had a much higher percentage of deaths from diphtheria than the Berlin town practice. This was because, broadly speaking, only serious cases were brought to the hospitals. But since the introduction of the serum treatment, a far greater number of cases—and cases of all sorts—had been brought to the hospitals, and so it was quite natural that the percentage of deaths had fallen considerably. He considered the serum treatment to be based on fallacies very similar to those which had formed the foundation of the tuberculin treatment. It would be interesting to find out, he added, what action on the organism injection of pure indifferent serum would have. Dr. Hansemann, in a few last words, stood to his view that antitoxin is not to be regarded as a specific for diphtheria.

The Sixty-third Annual Meeting of the British Medical Association will be held in London on Tuesday, Wednesday, Thursday, and Friday, July 30th, 31st, August 1, and 2, 1895. *President*, E. Long Fox, M.D. Oxon., F.R.C.P., Consulting Physician to the Bristol Royal Infirmary, Eng. *President-Elect*, Sir J. Russell Reynolds, M.D., Bart., F.R.C.P., F.R.S., President of the Royal College of Physicians.

The New York County Medical Association.—At the meeting of the New York County Medical Association, held December 17th, a resolution was adopted protesting against the appointment by Governor-elect Morton of a homœopathic practitioner to supersede Dr. Joseph D. Bryant in the position of Surgeon-General of the State.

Reviews and Notices.

Food and Feeding. By Sir Henry Thompson, F.R.C.S., M.B. Lond., etc. Seventh Edition. Partially rewritten and considerably enlarged. London and New York: Frederick Warne & Co.

Large editions of this book upon food and feeding, one of the most important and interesting branches of study, have been demanded by an appreciative public during the past few years. Since the original work was first published, a more general interest in the subject has been awakened everywhere in the English-speaking world, and a wider knowledge has become necessary. To meet this progressive spirit, whole parts of the book have been rewritten and valuable additions introduced in the form of notes, new chapters, an appendix, and methods and principles of practical cookery. The seventh edition of this well-known standard work is essentially modern and of the most penetrating simplicity. It is a convincing argument in favor of good living, of the wise selection and right preparation of food that secures health and æsthetic happiness at table. Variety is scientifically commended, the relative value of ordinary articles of diet is considered, and the treasures of the *pot au feu* are revealed. The book is printed in convenient form, with marginal abstract notes of the text that facilitate its study and serve for ready reference. "Food and Feeding" is an authority for enlightened laymen who desire to live well and to know just how to do it in the best sense.

Home Treatment for Catarrhs and Colds. A Handy Guide for the Prevention, Care, and Treatment of Catarrhal Troubles, Cold in the Head, Sore Throat, Hay-fever, Hoarseness, Ear Affections, etc. Adapted for use in the Household, and for Vocalists, Clergymen, Lawyers, Actors, Lecturers, etc. By Leonard A. Dessar, M.D., Visiting Laryngologist to St. Mark's Hospital and to Mt. Sinai Hospital Dispensary, etc., etc. Illustrated. New York: Home Series Publishing Co. London: Baillière, Tindall & Cox. 1894.

Presuming it to be necessary and wise to place instruction for self-treatment in the hands of the people, it is self-evident that the instruction should be reliable. In the little volume presented the author shows himself familiar with the conditions discussed and the ways to relieve them. The style is such that anyone can understand.

Physiology for Beginners. By M. Foster, M.A., M.D., F.R.S., Professor of Physiology in the University of Cambridge, and Lewis E. Shore, M.A., M.D., Fellow of St. John's College, Cambridge, and Senior Demonstrator of Physiology in the University of Cambridge. New York and London: Macmillan & Co. 1894.

This is a very elementary work for those having no previous knowledge of the subject, written by Dr. Shore and supervised by Dr. Foster. Illustrations are freely scattered through the pages, some borrowed, some original. Considering its aim, it is not a bad little book.

Essentials of Chemistry and Toxicology. For the use of Students in Medicine. By R. A. Witthaus, A.M., M.D., Professor of Chemistry and Physics in the University of New York; Professor of Chemistry and Toxicology in the University of Vermont; Member of the Chemical Societies of Paris and Berlin, etc. Twelfth Edition. New York: William Wood & Co. 1894.

How essential this quiz-like *vade mecum* has become to the student is indicated by the edition already reached. The chief changes to be noted are the arrangement of many of the alkaloids in their proper classes, and rearrangement of the carbon compounds. Advances in physiological chemistry have been noted. While some parts have been rewritten the bulk of material remains the same.

The little work belongs to the Wood's Pocket Manual Series, and is of the same size and style as the Cutaneous and Venereal Memoranda, etc.

Report of the Section on Surgery and Anatomy, at the Forty-fifth Annual Meeting of the American Medical Association, Held at San Francisco, Cal., June 5, 6, 7, and 8, 1894. Chicago: Journal of the American Medical Association. 1894.

This is a collection of the addresses, papers, and discussions. The first address by the Chairman, Dr. J. B. Roberts, is entitled "Some Surgical Sins." Many others are found in the succeeding four hundred pages.

Practical Urinalysis and Urinary Diagnosis. A Manual for the use of Physicians, Surgeons, and Students. By Charles W. Purdy, M.D., Queen's University, Fellow of the Royal College of Physicians and Surgeons, Kingston; Professor of Urology and Urinary Diagnosis at the Chicago Post-Graduate Medical School; author of "Bright's Disease and Allied Affections of the Kidneys;" also of Diabetes, its Causes, Symptoms, and Treatment. With numerous illustrations, including photo-engravings and colored plates. Philadelphia: The F. A. Davis Co., Publishers. London: F. J. Rebman. 1894.

He who tests his patient's urine—and this should include to-day all physicians who do not have the work done for them—must often feel the inadequacy of many of the smaller works on urinary analysis. Before one has read many pages of the book here described, a feeling of security is experienced. The test you have been looking for is found, or the facts about acetonuria which you lacked are given; or the ptomaines and toxins about which you desired information are discussed. The many new tests for albumin which have appeared from time to time, you are pleased to find here collected together. The clinical significance of the various deposits is found to be a valuable feature of many chapters. Then in Part II. Urinary Diagnosis is given a hundred pages, and this is followed by an appendix on examination of urine for life insurance. The type is clear, the illustrations are fairly good, and altogether it is a very practical work.

Atlas und Grundriss der Traumatischen Frakturen und Luxationen, von Professor Dr. H. Helferich in Greifswald. Munich: J. F. Lehmann. 1895.

This is one of the excellent series of medical hand atlases in course of publication by Lehmann, of Munich. There are sixty-four lithographie plates, with one hundred and sixty-six figures drawn by Dr. Joseph Trumpp, with explanatory text by Professor Helferich. We hardly know which to praise the most, and can only say that text and illustrations are worthy of each other, the two together forming a handy and useful guide to the art of diagnosing and treating fractures and luxations in the various parts of the body. With this little manual one can hardly fail to comprehend the mechanism of bone injuries of whatever sort, and, having that well in mind, to institute the proper treatment.

Prosthesis in Germany.—According to a recent consular report, American artificial limbs would have a great sale in Germany were there agencies established there by the manufacturers. The German makers of artificial limbs are less ingenious than their brethren in America, the limbs are heavier, less convenient, and more durable.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, November 15, 1894.

D. B. St. John Roosa, M.D., President, in the Chair.

Amendment to By-laws Adopted.—The amendment to the by-laws, proposed by Dr. A. M. Jacobus, fixing the annual dues of members living in the State, but outside of New York and adjoining counties, at $5, was adopted unanimously.

Further Observations on the Treatment of Malignant Tumors with the Toxins of Erysipelas and Bacillus Prodigiosus.—Dr. William B. Coley read the paper and presented four patients cured by this method. (See p. 65.)

Dr. Charles McBurney said there was no denying the importance of the results in Dr. Coley's cases. If the number benefited or cured had been much less, the interest would still remain. It was difficult to be satisfied with the discrepancy which existed between Dr. Coley's results and those obtained by other observers. He should think, however, that a good many of the imperfect results could be accounted for by the imperfect material employed or want of proper selection of cases. It was hard to explain, too, why the same material injected in one case of sarcoma should stop its growth and even cause its absorption or disintegration, while in another exactly similar case it had no retarding effect whatever. Until a satisfactory explanation could be given for such facts, or more uniform results could be obtained, one was restrained from forming too sanguine an opinion of the future of the treatment.

Three Unsuccessful Cases.—Dr. McBurney's own experience with the method had been limited to three cases, and in all Dr. Coley had inspected the patients and approved of the trial being made. One was a case of giant-cell sarcoma occurring after amputation of the hip-joint for very large tumor of the femur. The treatment had been begun three weeks ago, and had been continuous, under Dr. Coley's observation, but without apparent result, for the tumor had gone on increasing somewhat in size. Another was a case of multiple sarcomatous tumors, some involving the skin, some lying underneath it, the whole number being great. As in the former case, the constitutional manifestations following the injections were marked, but the only effect upon the disease seemed to be that it had spread, and Dr. McBurney believed it had extended to the pleura. The third case was one of sarcoma of the neck which had extended down behind the sternum so far that he was able, by operation, only to partially relieve constriction of the trachea. This patient had been under treatment by the toxins of erysipelas three weeks. His dyspnœa had become less and the sarcomatous tissue had probably diminished.

Dr. George F. Shrady, who had been invited to take part in the discussion, was unable to be present, but sent a brief account of his successful experience with the treatment of inoperable sarcoma by the toxin method, limited to one case, carried out by Dr. Coley, and described in the paper.

The Wesley M. Carpenter Lecture; Important Facts Relative to Malignant Disease.—Dr. Joseph D. Bryant read the lecture from a written paper. It led up to the following conclusions: 1. The death-rate from malignant disease is constantly increasing in all civilized countries. 2. The death-rate is larger in cities, irrespective of transient fluctuations, than in the country. 3. In limited portions of the country and some cities the death-rate from malignant disease is inexplainably and disproportionately large. 4. The increase of malignant disease demands urgent consideration and prompt methods of combat on the part of all concerned. 5. Better post-operative prognosis can be obtained by proper demand for it and prompt action of the profession. 6. When considerations for health and strength shall excite the same degree of forethought and vigilance as does the desire for wealth and power, then the post-operative prognosis will be very much improved.

Dr. Bryant showed by elaborate statistics the steady increase in death-rate from cancer in Berlin, Vienna, London, New York, Philadelphia, England, America, and various other cities and countries. After making all possible allowance for errors, one could not but reach the conclusion that this increase was real and not only apparent. The increase in death-date had varied somewhat in different places, but the following was a fair representation: Ten years ago, of the total deaths, 2.67 per cent. due to cancer, whereas, during the last ten years it had increased to 3.54 per cent. In New York City the preceding ten years, 1.82 per cent.; the past ten years 2.78 per cent. If such a mortality were caused by cholera or small-pox, governments would bend their energies to check it.

The chief mode of dissemination of cancer in the afflicted was through the lymphatics. A collection of cases was given which showed that in a large proportion involvement of the neighboring lymphatics was recognizable; also the tardiness of patients with cancer in presenting themselves for treatment; the procrastination of physicians in removing primary cancer or in referring the patients to a surgeon; also the relative results of early and late operation, which was greatly in favor of the former. Prompt and thorough removal was necessary to cure, yet indifference, trepidation, and procrastination had characterized the action of patient and doctor in this very fatal disease. All should be vigilant, vigilant, vigilant!

Committee to Consider Cancer.—Dr. Herman M. Biggs: In view of the increasing frequency of malignant disease and the importance of early diagnosis and removal, I would move that a committee be appointed by the President from representatives of the surgical staff of the different city hospitals to consider, in a broad way, the subject of malignant disease, its causation and prevention, and to report to the Academy such measures as may seem conducive to early diagnosis and successful treatment.

Dr. Armstrong moved, as an amendment, that, since the physician saw these cases before the surgeon, certain prominent physicians of the city should constitute a part of the committee.

Dr. Biggs accepted the amendment and the motion was adopted. The President said he would appoint the committee later.

The President announced the anniversary oration on November 28th, by Dr. Dana, and that the two meetings in December would be devoted to papers on the important subjects of diphtheria and bicycling, while at the succeeding one Dr. Lewis A. Sayre would read a paper.

Fast Living. — The most remarkable instance of rapid growth is said to be recorded by the French Academy in 1729. It was a boy six years of age, five feet six inches in height. At the age of five his voice changed, at six his beard had grown, and he appeared a man of thirty. He possessed great physical strength, and could easily lift to his shoulders and carry bags of grain weighing two hundred pounds. His decline was as rapid as his growth. At eight his hair and beard were gray; at ten he tottered in his walk, his teeth fell out, and his hands became palsied; at twelve he died with every outward sign of extreme old age.—*Times and Register.*

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, January 3, 1895.

D. B. St. John Roosa, M.D., President, in the Chair.

Annual Reports.—The annual reports of the trustees and other officers were read. It appeared that the new electric light plant, for which $3,000 had been appropriated, had been completed at a total expense of $2,000. The light was better than when the current had been obtained from the street wires, and the saving yearly would be about six hundred dollars. The sum of $125, paid Dr. Bryant for the Wesley M. Carpenter Lecture, had been presented by the lecturer to the library fund. By the report of the Committee on Admissions it appeared that seventy-three applications had been before the Committee during the year. Forty-six resident fellows had been added to the membership. The President said the work of this Committee was very arduous, and the members deserved much credit for the conscientious and satisfactory manner in which they had discharged their duties.

The report of the Committee on Library showed an accession to the library during the year of 780 volumes, also many journals and pamphlets. They had bound 891 volumes. The year had been marked by the addition of the finest stack-room in the country. There was great need of an endowment fund, since at present the library, which was also open to the public, had to depend almost entirely on the Academy for an appropriation to meet running expenses. A more liberal appropriation was necessary to meet the wants of readers, and the Committee asked for $6,000 for the present year. The Council, however, felt that this amount could not be granted, and recommended $4,500, and on motion the recommendation was adopted by the Academy.

Dr. A. B. Judson, Statistical Secretary, reported the death of Dr. William Detmold, at the age of eighty-five, one of the founders, and three times elected Vice-President.

Election of Officers.—The following nominees having received a majority of a total vote of 219 were declared elected: *President*, Dr. Joseph D. Bryant; *Vice-President*, Dr. W. M. Polk; *Recording Secretary*, Dr. R. H. Sayre; *Corresponding Secretary*, Dr. M. A. Starr; *Treasurer*, Dr. O. B. Douglas; *Trustee*, Dr. George L. Peabody; *Member of Committee on Admissions*, Dr. J. H. Fruitnight.

History of the Treatment of Spondylitis and Scoliosis by Partial Suspension and Retention of Plaster-of-Paris Bandages, and the Present Status of this Plan of Treatment before the Profession of the World.—The author, Dr. Lewis A. Sayre, said that when the President invited him to read a paper before the Academy, it had occurred to him that it would be appropriate to give a *résumé* of this plan of treatment and its position before the profession of the world. Some advocates of the method had gone so far as to claim much more for it than he had ever done. Regarding its origin, he said that for many years he had been in the habit of treating his patients with the Taylor brace, but for those who were too poor to pay for this he applied a "turtle-shell back," consisting of plaster of Paris put on by bandages extending part way around the body and covering the back, while the child lay extended across his knee. Twenty years ago, or in 1875, he first applied the plaster-of-Paris jacket by extending the bandages entirely around the body. At first he had fear of the influence on breathing, but experience showed it was unfounded. The first case was in a boy with Pott's disease, attended by partial paralysis of the rectum and one leg. It was noticed that motion was freer when he was suspended in the hands of an assistant, and that he breathed easier. Ever after that, suspension was employed during the application of the jacket. With the jacket on, the boy was able to walk about.

Dr. Sayre impressed the necessity for attention to detail in the application of the jacket, suspension only to the degree of comfort to the patient, a neatly fitting shirt, smooth application of the bandage, care in preparing the rolls, etc. The jacket ought not to be varnished, else it would become impervious to air, and cause excoriation and discomfort.

When this method of treating spinal troubles was first introduced by Dr. Sayre, twenty years ago, it was received with enthusiasm. In order to learn how it stood before the profession to-day, he had addressed a circular to one hundred orthopœdists and others in various parts in the world, especially Europe and the United States, with the exception of New York City, where it was expected the members would speak for themselves. Many replies had been received, but Dr. Sayre had time to read only a few, and selected those which criticised the method. In the first place, regarding scoliosis, or lateral curvature, he wished to protest against speaking of his method as consisting in applying a plaster-of-Paris jacket and leaving it on for three, four, or more months. Some patients could be cured by gymnastic exercise without any mechanical support whatever, but in other cases artificial support was necessary until the patient could gain voluntary control, and in some this support might have to continue through life. But the jacket should be removable, to permit of systematic exercise. In Dr. Sayre's experience it afforded the best mechanical support where support was required, although the greater number of criticisms received had related to its use in these cases of lateral curvature. He used the hammock, instead of suspension when applying it, only in cases of heart disease and great weakness.

Some of the gentlemen whose responses were read in part or whole were, Drs. Robert Jones, Bernard Roth, Noble Smith, Kinsley, Hodges, Young, T. G. Morton, Goldthwaite, Scudder, Lovett, Bradford, Vander Veer, Ward, Burton, Cook, Roswell Park, More, Hunter McGuire, De Forest Willard, Wilson, Andrews, Wright, Goldenberg, and others. Six had condemned the method entirely, seven used it in certain cases, thirty-eight employed it to the exclusion of all others.

About all the objections offered had been set forth in the letter of Dr. Noble Smith, who said that plaster-of-Paris jackets ought to be utterly condemned, 1, because of their great weight; 2, their interference with free respiration and cleanliness; 3, the fact that they acted simply as heavy, unscientific corsets, pressing upon the chest and adding very little to the support of the spine.

Dr. Sayre answered these objections by saying that a plaster-of-Paris jacket, properly made, was little heavier than a steel support, and in many instances was lighter. Any embarrassment to the respiration was due to the disease, not to the jacket when this was properly applied and not varnished. This even reduced such embarrassment by taking off pressure from the seat of disease and relieving pain. There was no trouble as to cleanliness if the patient were clean before applying the jacket. The accumulative evidence of many physicians was a better refutation than anything he could say of the charge that the jackets were heavy, unscientific corsets, pressing upon the chest and adding very little to the support of the spine.

Of the various substitutes, silicate of soda was light, but it was long in hardening, and did not permit of the insensible perspiration and circulation of air which could take place through plaster of Paris. Celluloid, wood, aluminum, and some other materials were lighter, but were also impervious to air, were more difficult to adjust, and were beyond the reach of persons of small means. But the point for which Dr. Sayre contended was the principle of the treatment, consisting in adapting to the body some plastic material in a position in

Pott's disease to secure the greatest comfort, and in lateral curvature to correct the form. The material of which the jacket was constructed was not essential so long as the principle was carried out, although he thought that in the vast majority of cases plaster of Paris would be found to be superior to other material on account of its cheapness, ease of application, and other facts. Whitman's shoulder-brace was mentioned favorably in certain cases.

Favors the Plaster Jacket.—Dr. Virgil P. Gibney was asked to open the discussion. He belonged to the class who had written Dr. Sayre in favor of plaster, and he had nothing whatever to say against it, but had a great deal to say against the abuse of it, but not on this occasion. He believed there was no instrument so universally serviceable as the plaster jacket. He used plaster not only in Pott's disease, but in hip disease, disease of the knee, ankle, shoulder, elbow, wrist, and was an ardent advocate of it.

Dr. A. B. Judson wished to add his contribution to the fund of respect which Dr. Sayre had exacted from the world by his labor and enthusiasm during a professional life of over half a century. The plaster-of-Paris jacket had had great popularity and success. It had brought relief in an important degree to a large number of patients and had been a welcome gift to the physician confronted with a case of Pott's disease and remote from an instrument-maker. Before the demonstration made by Dr. Sayre a physician so situated was unable to give mechanical support to the diseased spine, but with the plaster-of-Paris jacket he could treat the patient himself and at once. This jacket, however, does not allow the fine adjustments which are so desirable in the progress of a case of Pott's disease. Its great merit is that it can be applied easily and quickly. But the nature of this disease and the difficulty of its mechanical treatment justify the lavish expenditure of time and attention. The careful adjustments which we can make with soft steel enable us to give the necessary coercion to the bones of the spine and to preserve to the full the comfort and convenience of the patient. We often hear aluminum spoken of as the coming metal for orthopedic uses, but while waiting for it we may well be glad that we have the commercial steel of the present day, whose fine qualities were unknown ten or even five years ago.

Dr. R. W. Townsend believed firmly that plaster of Paris was the best dressing for the majority of patients, and by all means the best for use by the majority of practitioners. Other material, as aluminum, applied properly, would be better for certain cases.

Dr. H. L. Taylor thought that, owing to its cheapness and convenience of application, the plaster-of-Paris jacket had relieved thousands of sufferers who would otherwise have been left to their fate. Its action, he thought, was as an antero-posterior support, but it lost its leverage when it became loose. He preferred a properly adapted steel apparatus, on account of its greater precision, adjustability, and cleanliness. Among orthopedists the jacket was, he believed, taking a secondary position, while those who endorsed it enthusiastically were general surgeons and men who had no experience with braces.

Dr. Royal Whitman used plaster of Paris mostly in disease of the middle and lower region of the spine.

Garbage Should be Burned.—The Section on Public Health, through Dr. Armstrong, asked permission to promulgate a resolution condemning the present method of disposing of garbage and advocating incineration. The motion was adopted.

Professor Carl von Noorden, recently of the University of Berlin, has been appointed physician-in-chief of the City Hospital in Frankfort-on-Main, one of the best appointed hospitals in Germany.

OUR LONDON LETTER.

(From our Special Correspondent.)

ANTITOXIN SERUM TREATMENT—EIGHTY HOSPITAL CASES—RESULTS STATED AT CLINICAL SOCIETY—ADJOURNMENT OF DEBATE—PROPOSAL TO PATENT ANTITOXIN—THE SPECIAL MEETING OF THE CLINICAL SOCIETY—ADJOURNED DEBATE ON THE ANTITOXIN TREATMENT OF DIPHTHERIA—RESULT—COMMITTEE APPOINTED.

London, December 21, 1894.

There is no lack of subjects for a medical correspondent just now, but among them all the serum treatment holds the field. The English reports published up to last week were those of private practice, but the result of a long series of cases at the Eastern Hospital were given at the Clinical Society last Friday—this day week—in a careful paper read by Drs. J. W. Washbourn, E. W. Goodall and A. H. Card. The serum used was prepared by Dr. Ruffer, at the British Institute of Preventive Medicine, and was used in no less than eighty cases at the Eastern Hospital. No wonder that the announcement of this paper drew a large audience, and the debate upon it had to be adjourned to a special meeting which is being held to-night.

The writers of this paper began the treatment on October 23d, and continued it down to November 27th. Bacteriological examination was made of all the cases directly they were admitted into the hospital. In the majority of instances of true diphtheria the naked eye appearance of the cultivations was characteristic, the diphtheria colonies at the end of twenty hours being opaque and the size of a pin's head. The only colonies resembling them were those of a coccus described by Roux and Yersin, and called by them the "Brison" coccus. They differed in being more transparent and less prominent. It was rare, however, for other than diphtheria bacilli to grow in the tubes. In addition to the typical colonies other diphtheria colonies, much smaller and more transparent, frequently developed. Of the eighty cases examined, all of which were certified to be suffering from diphtheria, the typical bacilli were found in sixty-one. Eleven cases, which on admission presented the clinical aspect of true diphtheria, failed to give evidence of the presence of diphtheria bacillus. Only one of these died, and death was attributed to bronchitis. They found that the fewer the bacteria the better was the prognosis. In addition to the diphtheria bacillus they found straight bacilli of different sizes, comma-shaped bacilli, fine spirilla diplococci, streptococci, and other micrococci. In only seven cases were diplococci absent. No prognostic importance could be attached to the absence or presence or the number of these bacilli. Streptococci were found in more than half the cases, but their presence did not appear to influence the course of the disease. In about a third of the cases characteristic diphtheria bacilli could be distinguished in the exudation, and very few of these cases were of a mild type, and more than a third of them died.

Three cases were associated with "Brison" bacillus, two of these cases being mild, and one moderately severe. The good effects of antitoxin were manifested, (1) by a lessening in the amount of membrane, (2) by a notable fall in the pulse-rate, (3) an improvement in the general condition, and (4) a fall of temperature when this was raised. They noticed that after November 13th, the effects of the serum appeared to be more pronounced, and the dose was consequently diminished, and Dr. Ruffer was written to saying that this had been done. They had learned from him since, that the clinical quite bore out the experimental evidence, the fresh serum coming from a different horse and being at least five times as strong. So far only six patients had developed paralyses, and none of them severe. In six cases pain had been noticed in certain of the joints, the smallest dose to produce this being 10 c.c. The pain

lasted from one to three days, there being, except in one instance, pyrexia. The only local treatment adopted at the same time as the antitoxin was occasional flushing of the mouth and fauces with warm water.

Dr. Herringham said they had had 22 cases at St. Bartholomew's Hospital, of which 4 were doubtful, no bacilli having been found, 5 were severe, and 6 very severe. All the 11 required tracheotomy except one, in which intubation was performed; 4 were not tested, but in the other 7 the bacilli were present. Only 3 of these 10 cases of tracheotomy died, which was about half the usual average.

Mr. George Turner (Hertford) urged that when the bacillus was not found it did not necessarily follow that the case was not one of true diphtheria, a statement which, he said, was supported by the fact that these cases being introduced into the diphtheria wards, did not contract diphtheria. Dr. Burney Yeo asked whether any attempt was made to determine the precise period of the disease at which the treatment was commenced. That was important because, according to Dr. Roux and others, the results of the treatment were materially influenced by its being initiated early in the case. He asked incidentally whether English surgeons objected to intubation, as it was so little practised here.

At this point it was proposed by Dr. Ord, and seconded by Mr. Golding-Bird, that the debate be adjourned, and as it was evident that it could not be concluded that evening, this course was adopted. A special meeting was thereupon appointed for the continuance of the discussion. That meeting was fixed for to-night, but it will not be concluded in time to give any account of it in this letter.

In connection with this subject it may be as well to state considerable advance has been made here as to the supply of serum. There has been a difficulty in obtaining a supply, but that is being overcome. The British Institute is at work and will soon have more serum available, and there are other sources too, so that in the coming year a full trial will be made of the treatment in this country. Meantime it is reported that some smart commercial speculators are trying to patent the remedy. Considering that all the scientific workers have given their discoveries freely to the world, it seems a monstrous idea that any individual should attempt to grasp a monopoly of the process; and I should hope the only result of such an attempt may be to saddle the sordid speculator with a defeat and heavy costs.

London, December 28, 1894.

The debate on the serum treatment of diphtheria at the Clinical Society was resumed on Friday, 21st, when many interesting cases and statistics were re-reported. The testimony of those who gave their experience was decidedly in favor of the new treatment, especially when begun early, but even at a somewhat later stage the antitoxin seemed to exercise a favorable influence. The facts adduced seemed to offer no opportunity for criticism, and want of space forbids more than a brief report of the more salient points of the speeches made.

Dr. Golding-Bird said, surgeons were interested only in the question as to how far the use of antitoxin assisted in surgical measures necessitated by complications. They could not await the information afforded by antitoxin in the presence of these complications, because it admittedly took twenty-four hours to act. Albuminuria too, was, if present, by no means always indicative of diphtheritic nephritis. The author's mortality after tracheotomy, in cases treated by antitoxin, were three out of nine, equal to sixty-six per cent. of recoveries, the operation having been undertaken—this being an important point to bear in mind—not in view of possible contingencies, but because the child was actually menaced with asphyxia, was certainly satisfactory and even brilliant. He had performed tracheotomy in some sixty cases of "croup," and could only claim about from twelve to thirteen per cent. of recoveries. The difference between this or the nineteen per cent. which obtained among the author's patients prior to the use of antitoxin, and the six out of nine after its use, was very striking. The remedy presumably acted through the system, and if this were the case there must be a limit to the time at which it could be usefully employed. It would be useful to know what was this limit. He pointed out that suffocation was not so fatal in these cases as septic pneumonia, which was such a common complication, and asked whether antitoxin had any effect.

Dr. David Newman, of Glasgow, remarked on the difficulties of diagnosis, and gave some account of a case showing that the absence of bacilli did not prove that the affection was not diphtheria. In the severe epidemic of diphtheria in Glasgow during the last two months, he had seen a large number of the severer cases. The difficulty of ascertaining the exact strength of the serum employed was a drawback to its use, and he suggested that there must be some substance therein which could be separated. At present they were compelled to introduce a large quantity of serum which, from a therapeutical point of view, was useless. Still he had never seen the serum do any harm beyond the production of a rash within twenty-four hours following the injection. He had almost always found that the membrane separated much more rapidly after the injection than was usually the case, but he added that while using the serum he also continued the ordinary methods of treatment. The fall in temperature was sometimes as much as 3° when 104° or thereabouts, and less in proportion when the rise was less. The worst cases were those in which there was no rise, and in such cases antitoxin did no good. He stated that a nurse engaged in looking after patients suffering from diphtheria, at one time suffered from occasional attacks of sore throat, but after about two years these ceased, and since then, to encourage a child to eat, she would often eat out of the same dish, without contracting the disease. The serum he employed was Behring's.

Dr. Herbert Hawkins urged that in view of the many varieties of antitoxin now on the market, it was absolutely necessary for observers to state what particular serum they used. Aranson's antitoxin was a secret remedy, and differed from all the others in the smallness of the dose required. The method now employed by Dr. Klein was, he believed, the method formerly employed by Behring and discarded. He had endeavored to produce a supply of antitoxin for himself, and found it was possible to immunize a horse within a month by employing agar cultivations, the virulence of which had been attenuated by age. It was impossible to compare a fluid obtained in this way with that furnished by Dr. Ruffer, 5 c.c. of it absolutely and certainly protecting a 500-gramme guinea-pig against a treble full toxic dose of unattenuated virus. His experience with that fluid at St. Thomas's Hospital and the London Fever Hospital, had fully convinced him of the value of this method of treatment. He had never seen such rapid cures as followed its use. In two cases in which tracheotomy had to be done, the tube was removed at the end of three days, unusually early. In all the cases the typical bacillus was found. Both the fatal cases contained streptococci, and also a coccus which liquefied blood-serum in three or four days. The large dose of the remedy was a great drawback.

Dr. MacCombie said he had used, at the South-eastern Hospital, serum obtained from Dr. Ruffer on 31 cases, of which 3 died. Many of these were not "completed" cases, and one more, at any rate, would probably die. He admitted in all 54 cases of diphtheria, but he did not think it desirable to employ the serum in all. Of the whole 54, 7 died, giving a mortality equal to thirteen per cent. Nearly all the 54

were under fifteen, and all the 31 treated cases were. This was a lower mortality than he had seen before; but it was necessary to be very careful in drawing conclusions from a limited number of cases, extending over a short period. During the present year the mortality among cases under fifteen had been as follows: January, 21 cases, with a mortality of forty-two per cent.; February, 17 cases, with thirty-five per cent.; March, 16 cases, with thirty-one per cent.; April, 24 cases, with twenty-nine per cent.: May, 28 cases, with thirty per cent.; June, 32 cases, with thirty-four per cent.; July, 70 cases, with thirty-seven per cent.; August, 43 cases, with eighteen per cent.; September, 57 cases, with 29.8 per cent.; October, 48 cases, with twenty-five per cent.; November, 23 cases, with twenty-five per cent. There was thus a striking falling off in the mortality after July. Had the treatment been commenced in August, it might have been attributed to the serum. Apart from this, however, antitoxin certainly appeared to exercise a considerable influence on the course of the disease, especially when used early. He had not used it in any case that had been ill more than four days prior to admission, but he thought it should be tried in all cases, at whatever the stage, unless the patient was actually moribund. The serum appeared, in some cases, to prolong the irregularity which characterized the pulse in this malady. He had had one case of relapse twelve days after the first injection, in an adult. There was a rash in fifty per cent., but this might be due to the fact that he employed comparatively large doses. The rash was often accompanied by a rise of temperature. In only two cases were there subsequent joint pains. Though it was early to speak of paralysis, he was satisfied that this was less frequent than when the serum was not used.

Dr. Caiger's experience at the Southwestern Hospital, confirmed the results obtained by the authors. He had no doubt of the great usefulness of the remedy, but the important thing was to get the cases under treatment early. He had used it in all his cases admitted during the last three weeks, 30 in number, with 8 deaths; five of the eight died within twelve hours of admission, and three indeed within three hours, so that they were hardly a fair test. The proportion of these cases calling for tracheotomy was materially diminished by the treatment. The chances of paralysis developing, especially the early and fatal form, were admitted on all hands to depend on the extent and persistence of the membranes, hence the necessity of taking the cases in hand early. The type of disease during this period was unusually severe, the mortality at all ages being thirty per cent. It varied, in corresponding series, between fifty-two and twenty-seven per cent., but he had never seen it for two consecutive months as low as thirty per cent. His own experience agreed with those French observers, as to the presence of pyogenic organisms having an unfavorable influence on the prognosis, which, with pure cultivations, was mild. The description given by Dr. Washbourn, of what he called typical colonies, suggested colonies of streptococci and Brisson cocci, and he asked how he satisfied himself experimentally that these colonies were really of the diphtheria bacillus.

Dr. Tirard said Dr. Willcocks and himself, at the Evelina Hospital, had treated with Behring's serum eight cases, recognized clinically as diphtheria; bacteriological examination in several confirming the diagnosis. Albumin was present in some amount in all, together with a fairly large amount of membrane and marked depression. Of these eight cases one died, but at the post mortem erosion of the tonsillar artery was found. Two of the other cases were very severe, one so much so that tracheotomy had to be done at once, and the patient was so bad that they hesitated whether or not to risk wasting the antitoxin on the case. Both recovered, and the tubes were removed on the third day. The improvement under antitoxin was in all cases most striking. In one case a transient urticarial rash followed the injection.

Dr. Thomas Eastes said he had used Aranson's antitoxin in several cases, and he showed the temperature charts, indicating a marked fall after the injections. As the severity of a case was often an exchangeable term for duration, it was well to begin the treatment early. As his supply of the remedy was limited he only used it in severe cases. The first seven cases did satisfactorily. The eighth was apparently a mild case, but it got worse, and an injection was given. The child died suddenly, of heart failure, a week later. Two of the other fatal cases were dying of suffocation and required tracheotomy at the time of giving the injection. He did not think the serum really neutralized the toxins, or they would not get heart failure and paralyses developing several weeks later.

Dr. Sims Woodhead divided cases into two main classes: 1. Those in which the diphtheria bacillus preponderated, in which a fatal issue, if it occurred, did so early; and 2. those associated with streptococci, in which the fatal issue occurred later. They must be prepared to put up with the injection of comparatively large quantities of serum. It might be possible to render it stronger, but he doubted if it would ever be possible to separate and preserve, in an active form, a body which must necessarily possess a very unstable molecular composition.

The serum, as prepared by Klein's method, was quite a different substance to that prepared by Roux and Ruffer, and Dr. Klein, in view of this fact, proposed to call his preparation "antimycetin," considering that it had a greater action on the bacilli than on the toxins secreted by them. There were thus two distinct processes, one in which apparently, a virulent poison is formed at the site of inoculation, giving rise to a series of changes; another, induced by different poisons, apparently formed from the proteids of the body, which appeared to have a definite effect on the muscles and nerves corresponding to the changes which occur at a later period of the disease. This was on a par with the products used in such a disease as tetanus, the symptoms of which resembled those of a late stage of diphtheria. This fact might explain how it was that injections had been attended by so little success in tetanus, the disease having already reached an advanced stage before it came under observation. It would thus seem that the ordinary antitoxin only neutralized the poisons formed early in the disease.

Dr. Goodall, in reply, said they had noted the date of the disease in their patients as far as this could be ascertained; but as the information was necessarily second-hand and not altogether reliable, they did not think it desirable to complicate their conclusions by dwelling on this point. He had such a table, from which it appeared that out of 32 cases treated within three days of the commencement of the disease, only 2 died, whereas in 29 admitted between the fourth and the fourteenth day 11 died, so that there is evidently a very marked difference in the results according to the date at which the treatment was begun. It must be borne in mind that cases were met with that had been suffering for several days without appearing to be very ill, and he was not disposed to abstain from trying antitoxin in any case, for even in the cases which subsequently proved fatal the reaction was very marked. Mr. Lennox Browne had alluded to aneuria as, in his opinion, apparently caused by the injections, but everyone who knew anything about diphtheria knew that a tendency to aneuria was one of its commonest symptoms; it was indeed one of the direct effects of the diphtheritic poison. If the serum would determine nephritis, how was it that in none of the non-diphtheritic cases treated by serum was there albuminuria? (3) They had never seen a rash form as early as twenty-four hours after the injection, usually only after several days. On dividing the cases during 1893 into series of 72, the least mor-

tality had been twenty-five per cent., and the highest 45.8 per cent.; twenty-five per cent. was, however, the lowest ever reached, and in only one other series was it below 30 (twenty-seven per cent).

Dr. Washbourn also replied and said antitoxin did neutralize the diphtheritic poison, for this was the means by which they ascertained its strength. It was not, however, akin to the neutralization of an acid by an alkali, that is to say, it was not a chemical reaction. It seemed as if after the diphtheritic toxins had been some time in the body they underwent a change, and this might explain why antitoxin did no good in the later stages. He mentioned the case of a nurse who attended cases of diphtheria, in whom they found virulent diphtheria bacilli for months together without any affection of the health or throat. The extreme variations in the mortality commented upon by several speakers, would not obtain if sufficiently large numbers were taken.

At the conclusion of the debate, the President announced that it had been decided to appoint a committee to report on the serum treatment.

THE ORAL AND MANUAL METHODS OF INSTRUCTION OF THE DEAF.

To the Editor of the Medical Record.

Sir: You must allow me to call your attention to several serious misstatements which appear in an editorial article on the "Oral Education of the Deaf" in the Medical Record of December 8, 1894.

Professor Bell's essay on "A Possible Deaf Variety of the Human Race" makes no such claim as that "one-third of the children of deaf and dumb parents were congenitally deaf," nor do the statistics he presents warrant any such claim.

The number of intermarriages of deaf persons educated in manual schools is not greater than among those educated in oral schools. Professor Fay has not "persistently delayed" the publication of important statistics, and the reiteration of this charge by Dr. Miller, after he had been informed of its injustice, is greatly to his discredit.

My father was never "sent abroad to study the Braidwood system," nor did he go to Europe from Boston in 1817. Public-spirited citizens of Hartford, Conn., provided the means in 1815 for him to visit Europe and acquaint himself with the best available methods of educating the deaf.

It is wide of the mark to say that the "oral" method was never introduced into America until 1887 (an evident misprint for 1867). It was employed in the New York Institution as early as 1819; and beginning in 1855, the Institution at Hartford, the oldest in the country, had regular instructions given in speech and lip reading to many of its pupils.

Nothing could be further from the truth than to say that in 1868 I "called together in Washington a meeting of American manualists to take action against the new heresy"—the oral method.

In 1867, after a careful examination of the leading oral schools in Europe, I strongly urged in my published report the general introduction of oral teaching, and in the Conference of Principals held in 1868, just alluded to, I secured the unanimous adoption of the following resolutions:

"*Resolved*, That in the opinion of this Conference it is the duty of all institutions for the education of the deaf and dumb to provide adequate means for imparting instruction in articulation and lip-reading to such of their pupils as may be able to engage with profit in exercises of this nature.

"*Resolved*, That to attain success in this department of instruction an added force of instructors will be necessary, and this Conference hereby recommends to boards of directors of institutions for the deaf and dumb in this country that speedy measures be taken to provide the funds needed for the prosecution of this work."

The effect of these resolutions has been to secure the introduction of speech teaching into all the older and larger institutions of the country.

The Milan Congress of 1880 came very far short of settling "forever in Europe the question of how the deaf should be taught;" nor was it a "great Convention."

The teachers from Italy alone controlled the meeting by a clear majority. Italy and France furnished seven-eighths of its one hundred and sixty-four members.

The five American delegates, of which I had the honor of being one, who by a formal vote were the accredited representatives of fifty-one schools, containing over six thousand pupils, were allowed to be outvoted in the proportion of nearly ten to one by the forty-six representatives of the two schools of Milan.

The Milan Congress was a packed body, intensely partisan in its character, and its votes are entitled to no weight whatever in determining the relative merits of the methods that were there discussed.

Throughout Europe, especially in Germany and France, educated deaf-mutes, taught under the oral method, are to-day in great numbers protesting against the insufficiency of the oral method, and are petitioning the authorities to adopt important features of the manual method.

The effects of the "Report of Evidence taken before the Royal Commission in England" have been quite different from what would be inferred from the statements in your article.

The only public institution, so far as I am aware, which has been established in England since the report of the Commission was issued, is the Cross school, at Preston, the authorities of which did me the honor to say they had decided to adopt the American combined system on the strength of the evidence I gave before the Commission, and they informed me further, that they had been offered considerable sums of money by partisans of the oral method if they would make that the sole means of instruction.

Nothing could more utterly misrepresent the state of things in this country in regard to deaf-mute education than the statement that we are "going through the same scientific birth-pangs as did Continental Europe before the 1880 Convention of Milan."

Ever since 1867, when it was first suggested that the education of the deaf could be best carried on under a combined system, which should make use of all approved methods, the schools of this country have been coming to accept that idea. And in 1893, out of eighty-six schools in the United States and Canada, fifty-nine were using some form of the combined system.

In these schools there were seven thousand nine hundred and sixty-six pupils, out of nine thousand and fifty-two in all schools.

The pure oral schools numbered eighteen only, in 1893, with eight hundred and sixteen pupils, and during the present year, in one of them—the school at Portland, Me., with forty pupils, the combined system has supplanted the oral method, after a careful examination by its managers of the methods pursued at the best oral school (that of Northampton) and the best combined system school (that at Hartford) in New England.

In the combined system schools of the United States, speech is successfully taught to more than one-half of the pupils, while a great number of pupils, incapable of mastering speech, are afforded a good education by the use of the manual method. And nothing has been more clearly demonstrated of late years, both in this country and abroad than that the complete education of all the deaf cannot be effected under any single method. Those schools, therefore, which hold to the pure oral method, excluding all others, cannot assume

to meet all the requirements in the education of the deaf as a class.

Respectfully yours,
EDWARD M. GALLAUDET,
President.

"CHRONIC BILATERAL PAROTITIS."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In No. 9 of the last volume of the MEDICAL RECORD I find mentioned, under the above title, two cases of double parotitis, which Dr. Robert Abbe had reported in the April Meeting of the Practitioners' Society of New York. One of the cases had been seen in the practice of Dr. Robert F. Weir, who in the subsequent discussion made mention of another case lately observed by him. As the affection seems to be a very rare one it may not be useless to relate another case of this kind (even though I had not the good fortune to observe it to the end), the more so because this latter case may shed some light on the etiology of the trouble. At the end of February of this year, a young married woman called on me, complaining of a swelling of her eyelids, which had existed for a week. The œdematous swelling was symmetrical, most pronounced in the upper eyelids, but the whole region around the eyes appeared swollen and reminded me of the œdema that accompanies nephritis. There was no pain anywhere. She was not in her usual good health; in fact since the birth of her child, which she was still nursing, she had not regained her former good health. The examination of the eyes revealed nothing that could have explained the trouble; so I sent her with a letter to the physician who had confined her, for a general examination by him. He reported to me that the urine was normal, and in the absence of other symptoms he concluded that the œdema was due to "some trophic disturbance connected with a severe attack of migraine, which patient had had a few days ago." I did not see her again until eight weeks later, when she reappeared for an iritis of her right eye, of one week's standing. I was very much struck by her altered appearance. Both parotids were swollen to the size of a small fist. The swelling involved the whole gland and extended from in front of the tragus down to the angle of the jaw, where it was most prominent. The swelling was very hard, but painless, and hampered somewhat the mobility of the jaw. Patient told me it had appeared one week after her first visit, that is, seven weeks before her second; it had developed rather rapidly, but without pain. She felt very much "run down," and looked very pale. So I had an explanation for the œdema around the eyelids of seven weeks previously; evidently it had been an inflammatory collateral œdema foreshadowing the parotitis; now the parotitis itself demanded an explanation. The iritis was of the plastic variety, not very intense; without the unusual complication I would not have hesitated to consider it as syphilitic and to treat it as such. As it was, one could think of another possibility—metastatic origin of both iritis and parotitis from some malignant growth. I conferred with Dr. Julius Rudisch at that time in charge of the case (he happened to be the third since the beginning of the affection), an internal examination was agreed upon, but it did not reveal anything abnormal, so we decided upon energetic antisyphilitic treatment. The husband of the lady denied any specific affection in his own case, the baby was healthy, too, and, as I may add, has remained so so far; but he mentioned a recurrent skin affection of the hands from which his wife's father had suffered. I did not have the opportunity of following up the case personally, as at this stage the propensity to change doctors asserted itself again. I only know from the family physician that the patient consulted another oculist, whose diagnosis was likewise syphilis. His prognosis, however, of a speedy recovery was not entirely verified, as I was told that neuroretinitis supervened, and it took many weeks of energetic antisyphilitic treatment to cause the disappearance of the swelling of the parotides.

If it had not been for the appearance of the iritis, which pointed to the real character of the trouble, we would have been unable to make the correct diagnosis. I have inquired of a number of colleagues who have a vast experience with syphilis, but none had seen any cases of specific parotitis.

The handbooks on pathology mention syphilis as a possible cause of parotitis. Birch Hirschfeld says: "Parotitis is found as a secondary trouble in various infectious diseases, as in typhoid fever, scarlet fever, cholera, pyæmia. Also in syphilis, especially of congenital origin, parotitis develops."

Ziegler in his handbook expresses himself similarly. Since the above note was written Dr. Robert Abbe has presented his case of chronic bilateral parotitis again in the December meeting of the Practitioners' Society of New York (MEDICAL RECORD, No. 1, 1895, page 24), when the swelling had existed for eighteen months. The opinion of some of the gentlemen present was that it was a symmetrical lipoma.

Through the courtesy of Dr. Abbe I had an opportunity to see photographs of his case (which I have not had a chance to examine personally), and I can only say that the similarity in the appearance of that case to the one described above is striking.

CARL KOLLER, M.D.

715 MADISON AVENUE.

DR. GIRDNER'S TELEPHONE BULLET-PROBE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In last week's MEDICAL RECORD Dr. H. M. Wells, of the Navy, publishes what he calls an improvement on my telephonic bullet-probe. He says: "Dr. Girdner considers the body of the patient to be a sufficient battery for this purpose, but repeated tests of his instrument in the presence of several surgeons, convinced us that the current was not strong enough." Dr. Wells has reached this conclusion because he has not experimented with my bullet-probe, nor is there one of my instruments in the Navy Department to-day. He bought a number of cheap imitations of my invention some time ago, which unfortunately bear my name, but which are practically useless. I have sent word to Dr. Wells that the instruments he had bought were of no value, and offered to advise him as to the proper way to have them made; I also protested to the instrument-makers who furnished them, but all to no purpose; and I am glad of this opportunity to say publicly what I have often said privately, that so far as any good to the Navy Department is concerned, the money expended for these so-called telephonic probes might as well have been thrown into the ocean. Now, as to his alleged improvement on my instrument by introducing a battery-cell in the circuit. I had to experiment over a period of five years before I could bring the telephonic bullet-probe up to its present condition of absolute precision, and I went over the whole ground of using a battery-cell in the circuit outside the body, as Dr. Wells recommends. It is scientifically impossible to construct an accurate instrument if a battery is placed in the circuit outside the body, for the reason that accuracy depends upon the fact that no current shall pass through the receiver at the surgeon's ear until the probe touches the bullet; and that is exactly what happens in my instrument, and gives a loud response when the receiver is properly constructed, which Dr. Wells's is not. If a battery is introduced into the circuit outside the body, as Dr Wells suggests, and one terminal, the metal bulb, is placed in the patient's buccal cavity, and the other terminal, which is the probe, is passed into the

track made by the bullet, the merest tyro in electricity knows the circuit will be completed through the intervention of the tissues of the patient's body which lie between the bulb in the buccal cavity and the probe in the track of the bullet, and that a current will pass through the receiver at the surgeon's ear; and as the probe touches tissues of varying density and electrical conductivity, clicking and grating will be heard by the surgeon long before the probe touches the bullet, and will completely deceive him as to its location.

An instrument constructed as Dr. Wells suggests might work in experiments where the lead was simply held in the hand, but would be worse than useless in actual practice.

Dr. Wells says: "In experimenting with Dr. J. H. Girdner's telephonic bullet-probe, I had great difficulty in hearing the ticking when the probe came in contact with the bullet."

I am surprised that he was able to hear anything with the instrument he has. As to Dr. Wells's second improvement, viz., the bullet-forceps to serve both as probe and extractor, I have only to say that a better forceps for the purpose than the one shown in his article, was devised by the Surgeon-General of the State, Dr. Joseph D. Bryant, more than a year ago.

Soon after I had published this invention in the medical press, the Surgeon-General of the United States Army appointed Surgeon-Major John Van R. Hoff, U. S. A., to look into the matter, and make a report to him as to the advisability of adopting it in the service. Dr. Hoff called on me and I gave him every facility to satisfy himself in the matter. As a result of his report the Surgeon-General decided to include the telephonic probe in the regular surgical equipment of the Army. I told Dr. Hoff that the Navy had been unfortunate in getting useless instruments, and showed him one of the kind in use in that service. In order to protect the Army against this, and I think at Dr. Hoff's suggestion, I had carefully prepared drawings of every part of my instrument made, and also, detailed specifications of how they should be put together, etc., and these were placed on file in the Surgeon-General's Office at Washington. Now, when bids on contracts for telephonic probes are advertised for, one of the conditions imposed by the War Department is that the instruments shall accord in every respect with these plans and specifications in the Surgeon-General's Office.

The result of this is that, although there are ten times as many probes in use in the Army as the Navy, there has never been a single complaint about them from Army surgeons that I have known of.

A number of the most distinguished surgeons in this country and abroad have been using the telephonic bullet-probe for the past two years, and have not found the difficulty spoken of by Dr. Wells. One of these gentlemen, whose reputation is international, said in a public address, "I regard this probe as one of the greatest diagnostic means of the nineteenth century."

JOHN H. GIRDNER, M.D.

31 WEST THIRTY-EIGHTH STREET, NEW YORK CITY.

THE TYPHOID OYSTER.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Now that the oyster has won for itself fame in a new *rôle* as typhoid carrier, I may be allowed to suggest some means by which the dangers may be reduced to a minimum. I have not tried the method myself, but that is no reason why I may not induce others to do so who may be on the look-out for new ideas. If anything comes of it I reserve the right to claim priority by first placing the matter on record, and thus strike while the iron is hot. Therefore I would be pleased to have you publish this article at once, before some others thinking and working on the same subject may anticipate me. If I do say it myself, I think my ideas on the subject will tend to revolutionize the whole subject of bacteriology and open up ways for guarding against microbic infection through our food which have never before been put in practice. My modesty must be excused on the score of earnestness of purpose. I can illustrate my principle by applying it to the oyster.

Now, in the first place, the oyster must not be eaten raw. Aside from cruelty to the oyster it is positively unsafe. Six members of one family under my care contracted typhoid from one large raw oyster which each individual tried in-effectually to swallow in turn. This conclusively proved to me that the juice of the oyster was the sole cause of infection. No bacilli were found in the substance of the oyster save in such lacerated portions as were caused by frantic tooth indentations in efforts at swallowing. Even these were innocent in character and corresponded with those on the only remaining eye-tooth of the grandmother of the family.

These occurrences made a great impression upon my mind, the result of which is a sterilizing procedure which will reduce such dangers to a minimum. Indeed it will apply as a principle in all food-taking. First, then, the oyster, free from slivers, should be sterilized by steam, or boiled for one hour until it is reduced to one-tenth or one-twelfth of its former size. After this it should be enveloped in a sterilized napkin sprinkled with sterilized salt and pepper, smeared with thoroughly baked butter, and eaten with a fork previously heated to redness in a Bunsen's burner. Bacilli seldom light on hot iron, at least not to live long. It is, however, necessary to maintain a high temperature for the fork to be absolutely safe. There is no danger of burning the lips or tongue as the instrument is buried in the oyster, and with a wide mouth and an easy swallow the thing is done, and the fork is then heated again for the next customer.

All these precautions, however, will be useless unless the mouth, naso-pharynx, stomach, and intestinal canal are in a properly aseptic condition. Cavities in the teeth should be previously filled with sterilized wax, the mouth and throat rinsed with carbolized water, and ten minutes before the meal the stomach should be washed with sterilized water and a ten-grain tablet of bismuth naphthol should be taken.

Even then care must be taken to keep the mouth widely open to clear the beard and not to breathe or sneeze during the act of swallowing. Of course all this takes time and trouble, but only "eternal vigilance is the price of liberty" from diseases "which lurk around to hurry mortals home."

Please publish this in your next number, as I notice in a bulletin of our society that a friend of mine, to whom I unwarily communicated my discovery, is announced to read a paper on the subject, and thus with a generous rivalry in doing good to humanity, he is evidently determined to anticipate me.

Respectfully yours,

J. EARLY-HUSTLER, M.D.

POST CORNERS, CAL., December 28, 1894.

Microbes on Books and Tickets.—In his inaugural thesis (St. Petersburg, 1894), M. Trouskoliavski gives the results of his bacteriologic study of books used by hospital patients and of hospital visitors' tickets, as sources of microbic contagion. Microbiologic examination of newly-printed tickets and books revealed no microbes, but a similar examination of tickets that had been used, and of books that had been read by patients, showed an average of forty-three bacteria to the square centimetre. While many of these are innocuous, some pathogenic bacteria are found—streptococci, tubercle bacilli, etc.—and, affixed to the paper surface, these microbes are found to retain their morbific potency for a long time.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 12, 1895.

	Cases.	Deaths.
Tuberculosis	173	111
Typhoid fever	12	7
Scarlet fever	118	24
Cerebro-spinal meningitis	2	8
Measles	78	3
Diphtheria	225	56
Small-pox	6	1

Charcot, like Gull, physicked his patients very sparingly. If he did not, like Sydenham, recommend students to read "Don Quixote" as a part of their medical education, he thought the works of the so-called "naturalist" school of novel writers useful for other purposes. He used to prescribe certain chapters of Zola as the surest emetic known to him; other works of the same master and his disciples were in his opinion valuable as narcotics. He used to say the best shop for narcotics was at Medan (where the author of "Nana" lives); there an infallible "drowsy syrup" could always be got for 3.50 fr. To a student who, after a lecture in which erotomania had been touched upon, asked what was the best remedy for incontinence, Charcot replied, "anæmia—or better still, apoplexy." As regards anaphrodisiacs, the only one he had any confidence in was that used by the uncle of Heloïse in the case of Abelard. *Cela* (he would add with a grim smile) *tranche la difficulté.*

The Parts that do not Grow Old.—In his work on the senile heart Dr. Balfour tells us that there are two parts of the human organism which, if wisely used, "largely escape senile failure." These two are the brain and the heart. Persons who think have often wondered why brain workers, great statesmen, and others, should continue to work with almost unimpaired mental activity and energy up to a period when most of the organs and functions of the body are in a condition of advanced senile decay. There is a physiological reason for this, and Dr. Balfour tells us what it is. The normal brain, he affirms, "remains vigorous to the last," and that "because its nutrition is specially provided for." About middle life or a little later, the general arteries of the body begin to lose their elasticity and to slowly but surely dilate. They become, therefore, much less efficient carriers of the nutrient blood to the capillary areas. But this is not the case with the internal carotids, which supply the capillary areas of the brain. On the contrary, those large vessels "continue to retain their pristine elasticity, so that the blood-pressure remains normally higher than within the capillary area of any other organ in the body. The cerebral blood-paths being thus kept open, the brain tissue is kept better nourished than the other tissues of the body." Who is there among those who have reached or passed middle age that will not be rejoiced to find such admirable physiological warrant for the belief that the brain may continue to work, and even to improve, almost to the very last hour of life?

A Means of Preserving Urine for Analysis.—It occasionally happens that the busy practitioner is obliged to defer analysis of a specimen of urine until decomposition has rendered it valueless for his purpose. Dr. Huguet, professor at the Medical School of Clermont-Ferrand, states that urine can be kept for an indefinite period if to the contents of the vessel there be added 2 c.c. of the following solution: Mercuric cyanide, 10 grammes; water, 100 grammes. The addition of this salt does not alter the acidity of the urine, nor does it invalidate the results of the analysis. Chloral, which is often used to preserve urine, is said to interfere with the ordinary sugar tests.

Dry Surgery in Germany.—The American practitioners and students of medicine who have been trained to look upon irrigation as essential to the aseptic handling of wounds in their after-treatment, are always quite astonished at the apparent disregard the German surgeons seem to have for this method of securing good results. While in Göttingen, I was present every day at the surgical policlinic held daily by Professor Rosenbach, and I do not believe I saw a drop of water or other irrigation fluid used during the whole time. The patient is brought in, the dressings removed, the wound examined, squeezed lightly, oozing pus, is wiped off and dressings, dry or wet as may be necessary, are reapplied. Even in the treatment of deep abscesses, or where neurotic processes are going on, irrigation is never resorted to, the surgeon seeming to have all faith in his drainage-tubes without resorting to the stream of bichloride water as used by our American surgeons. They probably get just as good results here in Germany as we do in the United States, but their methods of wound-handling are certainly not so cleanly as those used in the latter country. — Berlin Correspondent of the *Memphis Medical Monthly.*

The Era of Dispensaries.—The history of English dispensaries has still to be written. It will form as interesting a volume as the story of the rise and fall of the private medical schools. Sir Samuel Garth may be looked upon as the first founder of dispensaries, for he promoted the erection of an apartment in the College of Physicians for the relief of the poor, by giving them advice gratis and dispensing medicines to them at low rates, as early as 1699. It was not until the last third of the eighteenth century, however, that they became really fashionable under the influence of Dr. Lettsom, physician and philanthropist in the truest sense. They were established for the relief of those who were too poor to pay for ordinary medical advice, and were yet not poor enough to accept gratuitous hospital treatment. The example set in London soon spread far and wide, so that the latter years of the eighteenth century may be known as the dispensary epoch in medicine, just as the present time is the special hospital epoch. Similar motives, no doubt, contributed to the foundation of both sets of institutions. In many cases it was a sincere desire to benefit the more deserving of the poorer class, but in many cases they were founded to the glory of an individual. The more worthy in each case have survived, but, by a process of natural selection, even they are becoming reduced in numbers. The records of one of the best of these institutions has just been written by Mr. Poland, with the laudable object of adding to its funds; and it would be well if the officers of other dispensaries would act upon the hint, and devote such leisure as they may have to a furtherance of the charity with which they are connected, by adding to its funds and writing its history.—*British Medical Journal.*

The Centenary of the Discovery of Vaccination.—The directors of the German Vaccine Institute are arranging a festal celebration, to be held in 1896, in commemoration of Jenner's discovery of vaccination. It will take place on the occasion of one of the annual meetings of medical men. In connection therewith there is to be an exhibition of old and new vaccine instruments, of apparatus for the preservation of lymph, etc., original manuscripts on small-pox and vaccination, on the inoculation of sheep-pox and cattle plague in pre-Jennerian days, of squibs on vaccination, medals, portraits, and autographs of prominent inoculators, vaccinators, anti-vaccinationists, etc. Persons willing

to lend objects for exhibition are requested to communicate with Geh. Med. Rath. Dr. L. Pfeifer, President of the Vaccine Institute of the Grand Duchy of Saxony, at Weimar.

Paris Students.—In the Faculté de Médecine at Paris there are 1,002 foreign and 4,142 native students; 195 of these students are women, of whom but 26 are French.

An Academy of Medicine in Washington, D. C.—A society of this name was formed at a meeting held on the 10th ult. After much discussion it was decided that it would not be successful if the Academy met in rented quarters, so the only plan which suggested itself as feasible was to procure from thirty doctors $300 each, in $100 yearly payments, with which the building suitable for the purpose was to be purchased and furnished. Many meetings looking to an organization were held, and all but one or two of the requisite number of subscribers secured; a constitution was adopted, and all seemed well until the advent of summer, when the enthusiasm died out and the matter was dropped. The meeting held on the 10th ult. was for the purpose of endeavoring to rescue the Academy, and as the other efforts had failed it was decided to raise only sufficient funds to rent a suitable hall and to furnish it. Temporary officers were elected until January 1st as follows: *President*, Dr. T. L. McDermott; *Vice-President*, Dr. F. C. Simpson; *Secretary*, Dr. J. L. Howard; *Treasurer*, Dr. J. M. Ray. A commodious hall has been rented in the Columbia Building, on the sixth floor; it will soon be furnished, and it is to be hoped that the profession at large will take an active interest in the movement.—*Journal American Medical Association.*

What Hot Springs and Hot Baths Will Do.—The United States Government has established a hospital at Hot Springs, Ark., for the treatment of soldiers and officers of the army. The hospital is now under charge of Surgeon Alfred A. Woodhull, who issues through the adjutant-general's office this circular; "Relief may reasonably be expected at the Hot Springs in the following conditions: In the various forms of gout and rheumatism, after the acute or inflammatory stage; neuralgia, especially when depending upon gout, rheumatism, metallic or malarial poisoning; paralysis, not of organic origin; the earlier stages of locomotor ataxia, or tabes; the early stages, only, of Bright's disease; diseases of the urinary organs; functional diseases of the liver; gastric dyspepsia not of organic origin; chronic diarrhœa; catarrhal affections of the digestive and respiratory tracts; chronic skin diseases, especially the squamous varieties; and chronic conditions due to malarial infection. . . . The Hot Springs water is contraindicated in all acute inflammatory diseases, tuberculosis, organic disease of the heart or brain, cancer and other malignant disease, aneurism, and all cases where stimulation of the circulation is to be avoided."

This seems to be a temperate statement of what hot water copiously taken, combined with proper hygienic surroundings, will do at Hot Springs, and we would add, at any place where pure water is supplied in abundance and at various temperatures.

Post-Mortem Parturition.—A remarkable case illustrative of this very rare occurrence, says *The Lancet*, is reported in the *Derbyshire Times* of October 30th, as having happened at Chesterfield. A single woman, aged twenty, who, as the event proved, was pregnant and nearly or perhaps quite at term, was seized with puerperal convulsions, and died undelivered. Apparently the fact of her pregnancy was unknown to those who were living in the house with her, and, indeed, a succession of fits seems to have given rise for a time to some suspicion of strychnine poisoning, a suspicion which subsequently was shown to be altogether without foundation. Now comes the remarkable part of the case. Two women who laid out the body in the customary manner, swore most positively that when they did so there was no sign of a child to be seen, nor any signs that would have led them to suppose the dead woman had been recently confined. It was decided to hold an inquest; and Dr. Green received the coroner's order to make a post-mortem examination. When he lifted the sheet which covered the body he found the body of a fœtus, at or near full time, beside the woman's body, and still remaining in connection with the placenta and uterus. There was an inversion of the uterus; there was also enormous distention of the abdomen. The woman had died on a Thursday morning, and the post-mortem examination was held on the Saturday afternoon, two days after the death. It might have been supposed that for some reasons of their own the women who laid out the body had determined to conceal the fact that there was a child's body there at the time as well as the mother's; but there seems no reason to doubt that they were speaking the truth, as, although the occurrence of parturition after death is exceedingly rare, still a sufficient number of cases are recorded to place the possibility of its occurrence beyond dispute. Thus, in a paper read by the late Dr. Aveling before the Obstetrical Society of London, forty-four such cases are referred to, and some particulars are given of thirty of these cases. The rarity of the occurrence, however, is shown by the fact that twenty-three of the thirty cases have had to be sought for in records previous to the beginning of the present century.

The First Meeting of the Association of Superintendents of Southern Hospitals for the Insane was held in Birmingham, Ala., November 20th, with Dr. J. T. Searcy, President, in the chair.

ACQUIRED IDIOSYNCRASY FOR QUININE, SHOWING PECULIAR CUTANEOUS MANIFESTATIONS.[1]

BY CHARLES W. ALLEN, M.D.,

NEW YORK.

SURGEON TO THE CITY HOSPITAL, GENITO-URINARY DIVISION; VISITING DERMATOLOGIST TO THE RANDALL'S ISLAND HOSPITAL, ETC.

THE skin eruptions which follow the use of the cinchona barks and their derivatives possess a double importance from the wide-spread employment of these drugs and their consequent liability to occasion frequent rashes, and the fact that, although the literature of the past ten years, at least, is not lacking in reports of cases, many of them show that the drug had either been persisted in for some time after the skin manifestations have appeared, through ignorance of their nature and cause, or else that it has been administered for a second time, and then only when the same eruption showed itself again has its origin been suspected.

It is for this reason that I venture to consume a little of our time in the report of a case possessing, it seems to me, some features of interest; and I hope the discussion will aid in the elucidation of some points which we must admit are unsettled, concerning the action of the drug in producing those phenomena with which we are familiar.

All of us have seen instances of pruritus due to quinine in which no exanthem shows upon the surface. I can recall a number of cases in which this tendency manifested itself in more than one member of a family; thus, a father and daughter, a mother and son, will have the same peculiarity, and I have repeatedly had patients tell me they could not take quinine, nor could one or the other parent before them.

The most frequent form of eruption resulting from quininism is probably the scarlatinoid, an erythematous rash beginning usually upon the face, and subsequently extending over the whole surface. Other usual forms are the urticarial and papular, while the vesicular, bullous, and purpuric are less frequently encountered; and last of all come the gangrenous forms. Dr. Van Harlingen, in his interesting and instructive paper on "Medicinal Eruptions," read before this Association in 1880, says that in exceptional cases the eruption may not become generalized, and Dr. Morrow uses the same words in his well-known monograph, in which is incorporated a paper written by himself, also in 1880; both agreeing that the erythematous is the prevailing type of eruption. Dr. Morrow found thirty-eight out of the sixty cases analyzed to belong to this variety.

The case I now report differs from the majority of those found in literature (1) in that the eruption occurred in a subject who had previously always been able to take quinine in moderately large doses (gr. v. to gr. xv.), and had never before suffered in any way from its use. (Dr. Morrow refers to this acquired idiosyncrasy in a case of his own.) (2) In that the eruption is developed by a smaller quantity of the drug than I have been able to find recorded in any other previous observation. (3) In that the lesions are local and show no tendency to spread or to become generalized. (4) In that the location of individual spots is always the same, no matter what the dose. (5) In that the eruption was produced four times accidentally, and some fourteen times experimentally. (6) And finally, in the fact that varying with the dose, and possibly with other unknown conditions, the lesion, which is always primarily, and usually solely, erythematous, may become urticarial, œdematous, bullous, covered over with small vesicles, or converted into an excoriated patch. In other words, the simple, rosy erythema of one attack may closely simulate in another an erythema exudativum multiforme. The amount of irritation in one case being, it would seem sufficient to produce only a dilatation of the vessels and redness of the skin, while in another an exudation takes place which may either show itself as an œdema, or if fluid is poured out between the corium and epidermis, the latter may be raised into a bullous sac, or numerous small vesicles may spring up to stud the surface. A greater intensity of action, or the same degree exerted upon delicate parts, such as the prepuce in this instance, may cause rapid shedding of the epidermic layer, and leave exposed a tender, excoriated, and bleeding area.

In 1889 the subject of this sketch, while suffering from toothache, took a five-grain dose of the sulphate of quinine at bedtime. During the night there was decided general pruritus, and in the morning large, round erythematous blotches were found upon the backs of the hands, inner surface of the thighs above the knees, dorsum of the foot, glans penis and prepuce, as shown in the drawing on p. 99. With the exception of a blotch upon either side of the spinal column, opposite the third or fourth dorsal vertebra, the size of a fifty and a twenty-five cent piece, respectively, these were the only regions in which spots appeared in this or any subsequent attack. Having suffered from urticaria on two previous occasions from eating clams, the idea of this eruption being of the same nature was suggested to the man's mind, and not suspecting the drug, which he had often taken before in larger quantities, the dose was repeated. The symptoms became more pronounced, and by the next morning, when I saw the eruption, the prepuce presented two large, oval excoriated surfaces, which became in a few days so suggestive of large chancroids that a colleague, to whom they were shown, suspected at first that this was really their nature. The rest of the region of the glans and prepuce was intensely red and sensitive. From the history (for I had never before seen just such an eruption from the drug) I made the diagnosis of exanthem due to quinine, and ordered its use discontinued. In about a week the spot began to desquamate, and continued to fade in color while peeling for about ten days longer. On July 2, 1890, again suffering from neuralgic pain in the teeth, patient took one "Mousette" pill, not knowing or not remembering that it contained quinine (about one grain). Within twelve hours itching, burning, and prickling sensations began, and the same spots as in the first instance showed themselves. Two days later the whole prepuce was excoriated as after a blister, and there were digestive disturbances. On July 6th the skin over the first phalanx of the little finger on the right hand was tender and looked like a burn. On the 9th the glans penis would bleed when irritated, while the prepuce was in a healing condition. By the 12th desquamation was

[1] Read before the American Dermatological Association at its Eighteenth Annual Meeting.

progressing in the various blotches. Again, in this same year, a cordial glassful of "Bougeaud" coca wine was taken and the same condition followed, though in a less pronounced way. The quantity of the drug must in this instance have been exceedingly small.

On August 18, 1891, patient took, in a drug store, a little elixir of calisaya with Vichy, the equivalent of quinine not exceeding one-third grain. Half an hour later well-recognized tinglings brought a realizing sense of the inadvertence. Within a few hours the spots had appeared, and the glans penis was encircled as by a ring of redness. There was no elevation of temperature. Two days later there was a bulla upon the little finger raised one-quarter of an inch above the niveau. Over some of the other spots were scattered miliary vesicles, and some spots showed enclosed rings resembling erythema iris. The bulla was pricked, and the serum allowed to flow off. The wall dried down into a waxed-paper-like scale. The skin beneath this was tender, and desquamation was repeated several times before the redness disappeared. Glans penis and prepuce became denuded of epithelium, and glans desquamated after healing had taken place. Thus it is seen that four times an eruption very similar in kind and degree followed the ingestion of quinine in varying quantity. Three times it may be said to have been accidentally taken after the first had demonstrated the idiosyncrasy.

In order, if possible, to clear up some of the things which are still unsettled concerning quinine eruptions, I now undertook a series of experiments with the co-operation of so favorable and, as he proved, willing a subject.

The statement has been made and repeated that it is the acid, and not the base, which is the offending substance in these cases, and that the individual who breaks out after the sulphate can take the citrate, for example, with impunity. To determine this point, at least so far as this case was concerned, and at the same time to test the efficacy of the tannate of quinine, which has been accused of being an inert preparation, I gave one chocolate tablet containing one grain of tannate, such as are prepared for children.

In exactly two hours a decided pruritus, tingling, and burning began to be felt in the region of the prepuce. This was found on inspection to be of a bright scarlet, as was also the glans penis. Stinging points were noted in the habitual regions, especially in the interscapular area. Scarlet blotches followed shortly in all of the usual situations. During the following day some of the hyperæmic patches became noticeably raised above the surface and somewhat œdematous, pitting upon pressure, while others were tender to the touch, and, as noted before, felt and looked like burned spots.

Allowing abundant time for the full effect of each exhibition of the drug to wear off, I tried in succession the hydrobromate or bromide of quinine in dose of one-quarter of a grain; the hydrochlorate, the bisulphate, dextro-quinine, and the bimuriate with urea (a soluble product for hypodermic use going under the name of quinine carbamide), all in the same dose. These were invariably followed by the same manifestations I have described, and when taken in connection with the recorded instances of eruption from the various other preparations, including the citrate, I believe the claim of Giampetro and others, that the acid and not the base is at fault, cannot stand.

Our next attempt was to find out whether the drug might not, by circulating through the lymphatics, be brought into contact with certain nerves of the skin or terminal nerve-filaments, and produce in them a local effect. To test this a tight band of adhesive plaster was bound about the wrist of the right hand so as to make decided pressure, and a dose of hydrochlorate of quinine was administered by the mouth. Despite this constriction, kept up for the whole of an afternoon, the spots appeared upon both hands as usual, and a little earlier, if anything, upon the right than upon the left. This experiment was repeated a month later by applying the constriction to the forearm, and after the hand was cyanotic injecting into the skin and subcutaneous tissues, between the hand and the band, one-quarter grain of the carbamide in solution. The effect of this was to produce after ten minutes an anæsthetic area the size of a fifty-cent piece, with slight and transient œdema, leaving behind an infiltrated condition of the skin with numbness of the whole back of the hand. For two days the site of injection was tender and the arm had a slightly lame feeling, but no erythema or eruptive signs of any kind appeared at the site of injection. The injection was made at noon, and at 12.20 the itching began to be felt in the prepuce. At 12.45 there was slight earache, a symptom noticed once or twice before shortly after a dose had been taken. At 5 P.M. the erythema began to appear on the prepuce and right hand, and at 8 P.M. on the left, followed by spots in the other usual locations.

On another occasion $\frac{1}{100}$ grain of the hydrochlorate was injected into the skin of the right arm, and an equal quantity into the hand at the site of one of the erythematous blotches, but aside from what might be expected from the injection of the same amount of water, there was no effect. I therefore came to the conclusion from these trials that the drug was incapable of acting in a local way, and that its action could not be confined to a given region, or prevented from entering this region by mechanical compression of the superficial vessels and lymphatics. They also showed that the theory of reflex dilatation of the vessels in the skin from stimulation of the sensory nerves of the stomach was not applicable here, unless we presume that enough of the drug is carried by the circulation to the gastric mucous membranes, when injected beneath or into the skin. But why should we presume that there would be primary irritation of the stomach nerves, if we are unable to produce this effect upon the skin nerves?

To test the effect upon mucous surfaces, one-quarter grain of the carbamide in solution was held by the patient in his mouth for fifteen minutes. No local effect of any kind was noted, and no general effect for six hours, when erythematous spots appeared in their old locations near the left knee, on the dorsum of the left foot, and upon the right little finger. These spots faded after two days and no others appeared. After some days the same quantity of the same preparation was made into a suppository with cocoa butter, and introduced just within the sphincter ani, where it was allowed to melt. No local effect whatever, but the general symptoms followed in quite a pronounced way after five hours, and the spots did not entirely fade for two weeks. If we consider the effects in these instances as reflexes from irritation of the digestive tract, should we not expect a rather quicker result than when we inject the drug into the skin? Such was, however, not found to be the case. To test the possibility of local effect from inunction, I had prepared an ointment containing two grains of the hydrochlorate in a small quantity of lanoline and lard. This was rubbed into the back of the patient's right hand for fifteen or twenty minutes. No local effect was appreciable, but about six hours later a distinct erythema of the corona glandis and prepuce appeared, with the attending pruritus, and lasted twenty-four hours. There was also irritability about the neck of the bladder, with frequent calls to urinate, and two days later a herpes præputialis developed, causing further trials to be postponed. The herpes was not looked upon as a direct effect of the quinine, but it was thought that it might be referred indirectly to it through the bladder symptoms. Patient stated that in former years he had been troubled with frequent attacks of herpes, but for six or eight years did not remember to have had it.

Although I am quite well aware that quinine in susceptible subjects often causes vesical irritation, I did

not lay great stress upon this instance, from the fact that this patient had often suffered in a similar way when he "catches cold," and when no quinine had been taken; and, on the other hand, in most of the eruptive attacks the bladder function had not been interfered with. Some time after the herpes had healed, four grains of the muriate, in ointment, was again rubbed into the hands for twenty minutes at bedtime. In the early morning there was thickening of the skin of the prepuce, redness extending over the whole glans, irritability of the bladder, and frequent urination, continuing for thirty-six to forty-eight hours, also slight sciatica-like pains in the right leg. The effect upon the hands was slight, the little finger being more affected than other parts, desquamation taking place several times in succession. There was no evidence that any local action had resulted from the inunction. I now became convinced that the vesical irritability did proceed from the quinine absorbed by the skin. Cases in literature show that this effect is recognized, and that hæmaturia even may be occasioned, just as it may be cured, by quinine. This may be homœopathic in principle, but the dose necessary for this result is usually far from being one of homœopathic proportions. Still, with the view of testing skin absorption, I had the man apply to the scalp with moderate friction a drachm of an alcoholic solution containing one grain of quinine. Twelve hours later there was erythema of the glans and upper surface of the prepuce, with decided tingling and burning, but no local change on scalp which could be charged to the drug. Subsequent daily applications of half this quantity did not seem to increase the intensity of the original effect.

This completes my observations in the case, but I have purposely omitted till now the mention of a symptom to which I am inclined to attribute some importance in determining the manner in which quinine may act in the production of cutaneous eruptions.

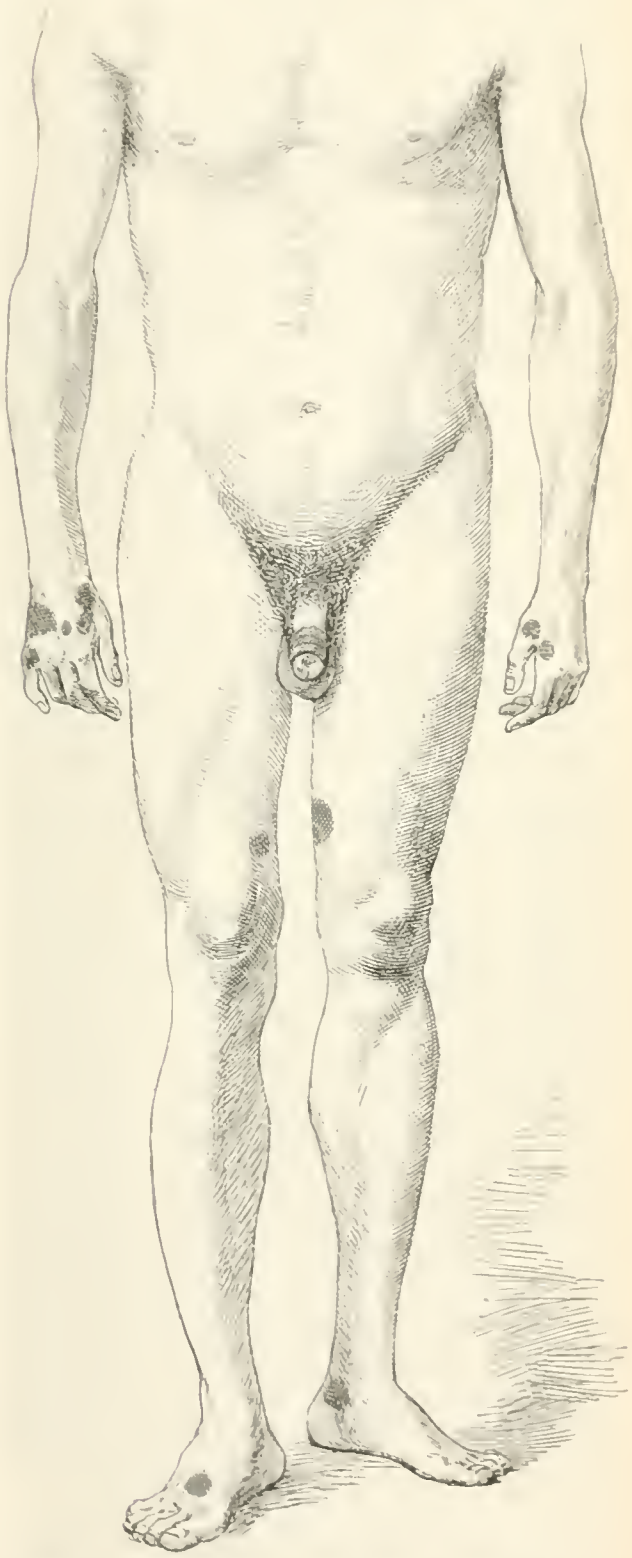
In the first and second attacks, in that brought on by the hydrobromate three years later, and in the last outbreak after rectal administration of the drug, complaint was made of a dull ache in the interscapular region. This was more pronounced in the early attacks. Examination on repeated occasions showed the undoubted existence of marked tenderness on pressure over the spinous process of the second dorsal vertebra. This tenderness would disappear as the eruption faded, and was never to be found in the intervals of quinine eruption.

Now, upon this symptom, indefinite as it may be, I pivot my proposition, or, may I say better, supposition, that the eruption is due neither to a pathological reflex direct from the digestive tract; nor to a direct effect upon the peripheral nerves; nor to the irritation produced locally upon the skin in the process of elimination of the drug by the glands; nor to its action as a protoplasmic poison upon the capillary vessels; but, on the contrary, to an angeio-paralysis of central spinal origin. Whether the drug undergoes chemical change before it is capable of producing these effects, I am unable to say, but from the rapid onset of pruritus I would argue that it acted in its unchanged state.

It is well known that quinine is eliminated by the sweat-glands as well as by the kidneys, but the constant symmetrical distribution, and circumscribed features of the eruption in this case, it seems to me, are much more rationally explained on the theory of nerve origin.

Again, in support of this we have an effect prolonged much beyond what one would expect from the irritation due to elimination. We know that quinine can be detected in the urine within ten minutes of its hypodermic injection, and that it may be found here for several days; but presuming the elimination by way of the skin to be likewise protracted, it would scarcely account for instances in which an active stage of eruption or apparent exacerbations continue for several weeks after the drug is withdrawn. If we invoke the direct local action of the drug upon the bladder-wall, for instance, to account for vesical irritation, we must presume that the drug has undergone some change in the system, since simple contact with mucous membranes, as I have shown, produces no irritation or local effect.

I cannot agree with Bouvard that skin elimination



explains all the eruptions, as he claims, excepting that of purpura, which may have its source in the action of the drug upon the blood and tissues.

That hyperæmia of certain regions follows a moderately full dose is shown, for example, by observing the ear-drum or the fundus of the eye; the fulness of the vessels indicating a corresponding intra-cranial effect. That the cerebral circulation is quickened is shown by

the exhilaration often secured by a comparatively small dose. Thus I have as a patient a reverend gentleman who is in the habit of taking two or three grains of quinine upon starting for church. The beautiful choice of words and eloquence of the sermon make the ears of his hearers fairly tingle, and not one of his congregation dreams that their tinnitus is produced by the preacher's cinchonized words.

Full doses, too, as is well known, will cause dilatation of the pupil similar to that from belladonna. These effects may all originate in the nerve-irritation. In large doses, Chapron says, the reflex function of the cord is lessened and ultimately abolished; and Wood has pointed out that convulsive attacks may follow.

If large doses can produce such marked results by acting upon the cord, why is it not rational to refer these skin changes to the same source?

The analogy which certain of these quinine eruptions bear to urticaria and circumscribed œdema, depending probably on innervation disturbances, must not be overlooked, especially the angeio-neurotic œdema that occurs in subjects of urticaria who are distinctly neurotic or give history of neuralgic attacks, etc. The vaso-motor disturbance here, as well as in certain quinine eruptions, is probably first spasmodic and secondly paralytic. I would also mention the somewhat analogous condition of symmetrical œdema and other trophic changes in the extremities, in those states in which the cord is known to be the seat of pathological change—I refer to syringomyelia, Morvan's disease, Raynaud's disease, etc.

The only case I have been able to find similar to my own was reported by Dr. Munn in the *Atlantic Medical and Surgical Journal*, in 1879. His patient always developed bright-red erythematous patches upon the left cheek, nose and chin, the palmar aspect of the left wrist, the back of the left hand over the carpo-phalangeal articulations of the fourth and fifth fingers, and the left knee. In his case, however, doses ranging from five to thirty grains were required, and the eruption only developed after the drug had produced its full effect on the system. The tendency ceased after an attack of pneumonia and did not return, thus showing that the acquired idiosyncrasy may fortunately be lost again.

I do not wish to enter into the matter of treatment, excepting to draw attention to what might be a misleading statement under this head in Morrow's "Drug Eruptions." The author says, "Treatment is hardly ever necessary for the cutaneous disorders caused by quinine, since they spontaneously disappear on withdrawal of the offending agent. This might lead to the supposition that the rash would be gone the day after the quinine was stopped, whereas several weeks may elapse before the activity of the eruption and pruritus have ceased entirely. Indeed, the eruption may not even appear until after the drug has been withdrawn for some time. I have also been unable to verify the statement that women are more susceptible than men to quinine eruptions. My personal experience has led to the opinion that sex plays no part in their production, and that the cases are about equally distributed.

If there is anything in this theory of spinal irritation, it may have an importance not only as bearing upon the etiology of certain obscure skin affections, but also as offering a possible explanation of the way quinine acts in producing some of its therapeutic effects.

The Medical Profession in Glasgow.—The *Medical Press* says that a certain section of medical men in Glasgow are simply traders in corn-plasters, pink pills, snuff, tobacco, tooth-brushes, pomades, and the like, and that there is a lamentable absence of *esprit de corps* and self-respect among a certain class of practitioners in Glasgow. It is difficult, our contemporary adds, to acquit the Faculty there of a share of the responsibility for this condition of things.

ON THE SURGICAL TREATMENT OF UTERINE FIBROIDS, WITH THE REPORT OF TWO CASES OF SUCCESSFUL ABDOMINO-UTERECTOMY.[1]

By WINSLOW ANDERSON, M.D., M.R.C.P. Lon., Etc.

ADJUNCT TO THE CHAIR OF THE PRINCIPLES AND PRACTICE OF MEDICINE, UNIVERSITY OF CALIFORNIA MEDICAL DEPARTMENT, ETC.; EDITOR OF THE PACIFIC MEDICAL JOURNAL.

The frequency with which fibroids invade the uterus has not been determined. Fritsch states that nearly every tenth woman has one or more fibroid tumors of the uterus. Bayle claims that fibroids occur in thirty per cent., and Kolb asserts that uterine fibroids occur in fifty per cent. of women over fifty years of age.[2] All of these estimates of the frequency of uterine fibroids are much too high, according to my own experience.

When Should We Operate on Uterine Fibroids?—There was a time, within the memory of living gynecologists, when uterine fibroids were regarded as wholly benign and almost sure to cease growing, if not to diminish in size, after the menopause. Contemporaneous with these views of twenty-five or more years ago, the mortality of abdominal hysterectomy was eighty per cent. These considerations had an important bearing on the question of when to operate for uterine fibroids. Now that the mortality has been reduced to one or two per cent., and it is known that uterine fibroids frequently cause the death of the patient either from repeated hemorrhage, exhaustion, pressure, renal complications, malignant or necrotic degeneration of the fibroid itself, and that oftentimes the tumors do not cease growing with the menopause, etc., the views regarding early operations have materially changed.

Martin, of Berlin, records 196 cases of fibromata in which 38 were found to have undergone retrograde changes.[3] In 205 cases of entirpation of myomatous uteri, Martin found 9 cases which showed carcinomatous, and 6 cases sarcomatous, degeneration. Leopold claims that fibromata may become fibro-sarcomata, and in one of his cases he observed carcinomatous formation within the myoma. Erendorfer holds that the mucose of a fibroid uterus may become carcinomatous.[4] Emmet states that in several instances under his observation fibroids underwent sarcomatous metamorphosis. Professor Klebs and Sir James Y. Simpson mention several similar cases.

I would advise the removal of uterine fibromata whenever they cause any of the following symptoms: 1. Severe menorrhagia or metrorrhagia. 2. Severe pain from pressure. 3. Repeated attacks of pelvic peritonitis. 4. Malignant or necrotic degeneration. 5. Size of tumor so large as to interfere with the patient's movements and usefulness. 6. Cystitis, dysuria, hydronephrosis from pressure on the ureters, severe hæmorrhoids, varicosities of the lower extremities, uncontrollable reflex nervous and nutritive disturbances. 7. Repeated miscarriages, tubal and extra-uterine pregnancies, and where the tumor seriously complicates the labor.

In these cases I believe operation is imperative, whether the tumor be the size of a walnut or as large as a fœtal head. To allow these symptoms to continue from month to month and from year to year, in the vain hope that the menopause will bring about a desirable result, is merely to reduce your patient's strength and remove her chances of recovery. To wait for a fibroid to grow to the size of a child's head before its removal, may mean the death of your patient either before or immediately after the operation. Dr. Irish records, in the *American Journal of Gynecology and Obstetrics* for December, 1894, ninety-four cases

[1] Read before the San Francisco Gynecological Society, December 20, 1894.

[2] Woman's Medical Journal, November, 1894.

[3] J. C. Irish in American Gynecological and Obstetrical Journal for December, 1894.

[4] Woman's Medical Journal, November, 1894.

of fibroids, in which forty-three of them "developed dangerous and formidable symptoms, in patients between the ages of forty-two and fifty." Calcareous, necrotic, pus-forming, cystic, sarcomatous, and carcinomatous degeneration may occur while waiting for the *vis medicatrix naturæ*. Abdominal surgeons are agreed that the dangers of the operation increase *pari passu* with the size of the tumor, the age of the patient, the reduction of her vitality, and the nutritive disturbances, etc., and that fatal cases are usually the neglected ones. Repeated severe hemorrhages, attacks of inflammation and adhesions, salpingitis, ovarian degeneration, incarceration of the tumor, in the pelvis, pressure on the ureters, hydronephrosis, extra-uterine pregnancy, degeneration of the tumor or malignant new-formation, are symptoms and complications that are apt to arise at any time; nevertheless, as Dr. Cushing, of Boston, said in a recent article, "Grim and lamentable cases still occur too often where, either from timidity on the part of the patient, or from bad advice and mistaken ideas on the part of her medical adviser, the time for favorable operation has passed by. The chances of recovery have been cruelly thrown away by miserable delay and worse than useless treatment, until the patient is delivered to the surgeon sinking under her burden, a subject for the hazardous and gruesome operation, and likely then to die, leaving grief to the friends, blame to the surgeon, and discredit to the profession."

Methods of Operation.—The following are the methods of operation for uterine fibroids, which are in vogue at the present time:

1. Vaginal Ligation of the uterine arteries, as practised by Franklin Martin, of Chicago, may, in some cases, be productive of good results by limiting the blood-supply of the tumor.

2. Removal of the Uterine Appendages, as advocated by Lawson Tait, Hegar, and others, establishes an artificial menopause and does no doubt, at times, limit the growth and prevent uterine hemorrhage. It is difficult, however, to comprehend why this operation should accomplish more than the natural menopause does, and as we know that in many cases the tumor continues to grow after the climacteric, it would seem that if more radical means were at the surgeon's command, it were better to avail one's self of them and avoid the grave dangers of a second operation, or those of malignant or necrotic degeneration of the tumor. A fibroid uterus left in the pelvis without the support that the appendages naturally afford, is also very apt to produce prolapsus, retroversion, and constant pain and annoyance.

3. Myomectomy, or the removal of the tumor, leaving the uterus *in situ*. This operation is applicable to submucous and subperitoneal fibroids. It is an easy and a safe operation, and should always be done in suitable cases. In the submucous variety the os is dilated and enucleation is accomplished per vaginam, by the finger or the snare, followed by the intra-uterine douche and iodoform gauze-packing. The subperitoneal variety can at times be removed per vaginam, although usually a cœliotomy will be required. Martin, of Berlin, uses a continuous catgut suture to reunite the peritoneal covering of the tumor. This, I believe, is of importance to insure rapid recovery and to prevent adhesions to the intestines. As fibroids are frequently multiple, especially the subperitoneal variety, care should be exercised to remove them all, so as not to require another operation in a twelvemonth.

4. Vaginal Hysterectomy is, by election, when enucleation cannot be done, the safest and best operation for uterine fibroids when it can be performed, and if cases were seen and diagnosed early, it is probable that most of them could be operated on by this method. Of course, the tumor must not be too large nor must the adhesions be too extensive. The clamp method is the most rapid, and in the hands of one of our distinguished Fellows, Dr. McNutt, it has proven eminently successful in a number of cases. The application of ligatures to the uterine and ovarian vessels and the closing of the vaginal vault is claimed to be the more scientific operation of the two. The appendages should always be removed with the uterus. When there are not many adhesions and the work is done aseptically, as it always should be, there is no need of drainage. Indeed, I believe we are better off without it, as there is always some danger of sepsis entering the abdominal cavity through a drainage-tube.

5. Abdominal or Supra-vaginal Hysterectomy becomes necessary for the removal of a fibroid when the size of the tumor will not admit of its removal per vaginam, and in cases where extensive adhesions have formed, or when the case is complicated by tubal or ovarian disease. Of the various methods of procedure now in use, the following are worthy of mention: Keith, Bantock, Péan, Tait, Price, Thomas, and Cushing, of Boston, as the operation of election, fix the stump in the external abdominal wound as in a Porro. Steel pins and the wire or serre-nœud are used. The pedicle is fixed into the external abdominal wound and charred with the cautery or dressed antiseptically. Excellent results are recorded by these great men, and it would, perhaps, seem presumption on my part to question the procedure. But if I were asked "Is this the most scientific and the most satisfactory method of treating a uterine pedicle?" I must say "No." Because it prolongs the healing process and keeps the patient in bed for several weeks. During the first week or ten days there is bound to be more or less sloughing. It leaves an unsightly scar, and patients are almost certain to complain subsequently of more or less annoyance, distress, and pain from tension, especially if the abdominal walls are thick. More than this, it is very apt to leave the patient with an undistensible bladder calling for frequent micturition.

6. Kelly's Method.—Kelly fixes the stump of the abdominal wound external to the peritoneum, but internal to the skin. This method has not been generally adopted.

7. Byford's Method.—Byford, and another of our distinguished Fellows, Dr. Mays, performs cœliotomy for the removal of the uterus and fibroid, and then fixes the pedicle anteriorly or posteriorly in an opening made in the vaginal vault, thereby obtaining free drainage per vaginam.

8. Schroeder and Brennecke's Method.—Schroeder and Brennecke treat the pedicle intra-peritoneally as in ovariotomy, and use abdominal drainage.

9. Leopold's Method.—Leopold uses transverse ligation of the pedicle and drops it into the pelvic cavity without drainage.

10. Zweifel's Method.—Zweifel treats the stump intra-peritoneally, using an interlocking stitch of silk in the broad ligament and catgut across the cervix.

11. Extra-intra-peritoneal Method.—Chrobak, Hofmeier, Baer, Goffe, Eastman, and others use the extra-intra-peritoneal method of treating the stump. The ovarian and uterine arteries are ligated on each side, and the peritoneal surfaces are united over the pedicle so as to leave it outside, practically, of the peritoneal cavity.

12. Eastman's Method.—Eastman, latterly, enucleates the entire tumor with or without the uterus, and stitches the serous surfaces together.

Keith remarks that in operating for a uterine fibroid the operation should always be begun with the intention of performing the intra-peritoneal method and removing the whole organ, if possible; but the operator must be prepared to adopt any method, should it seem best to do so, when the exact conditions are found out during the progress of the operation. This, I am sure, we will all consider very good advice.

13. Total Extirpation of the uterus is now practised by Martin, of Berlin, Stimson, Krug, Polk, Boldt, Ede-

bohls, and others. Martin, in his total extirpation, attaches the vagina to the peritoneum all round with catgut sutures, the ends of which are brought out through the vagina.

Jones uses the combined method of removing the tumor from above, and clamps the arteries and ligaments from below. Polk and Stimson use but four ligatures, one in front, one behind, and one on each side. These are tied together to form a vaginal vault, bringing the ends out of the vaginal outlet for drainage. Polk and Mann also recommend the use of a glass drainage in the abdominal wound.

The great danger of the intra-peritoneal, extra-intra-peritoneal, or any modification of the stump operation, lies in the fact that after the ovarian and uterine arteries are tied there is very little chance for blood-supply to the stump, and sloughing is apt to result. If, however, the vaginal vault is not disturbed and a V-shaped piece is cut out of the cervix, leaving but a mere shell of cervical tissue in the form of an anterior and a posterior flap which, if accurately brought together with their serous coverings and stitched with a continuous catgut suture, there need be little fear of sloughing. Nor do I think it necessary, as a rule, to have drainage so far as the stump is concerned, unless there have been extensive adhesions broken up leaving oozing surfaces in the pelvic cavity.

Leopold, in a recent article, epitomizes the results of all the cases of myoma upon which he has operated since 1889–90, as follows: Enucleation by the vagina, 46; mortality, 0. Castration (oöphorectomy) 40; mortality, 2.5 per cent. (1 sepsis, 1 heart failure). Myomectomy (abdominal hysterectomy) with intra-peritoneal treatment of stump, 21; mortality, 0. Myomectomy (abdominal hysterectomy), with extra-peritoneal treatment, 29; mortality, 2; 6.8 per cent. Vaginal total extirpation, 24; mortality, 0. Total, 160; mortality, 4; 2.5 per cent.

Report of Case I. with Exhibition of Specimen.—Mrs. S——, aged fifty-two, had been suffering from menorrhagia for about three years, and profuse metrorrhagia for the past two years. The hemorrhages occurring as frequently as once a week and latterly twice a week, lasting for one to three days. About one year ago she had a curettage done which relieved her for a month or two, but the hemorrhages again came on more profusely than ever. There was always considerable pain during the attacks. The patient was under my care for three months, during which time all the hæmostatic remedies were tried, with little or no beneficial effect.

On account of her age it was hoped that with the menopause the hemorrhage would cease of itself and the metro-fibroma disappear. The hemorrhage, however, became more and more alarming, so that it was at length decided to operate. Accordingly, the patient was removed to the Waldeck Sanatorium, and on October 14, 1894, with the valuable assistance of Drs. McNutt, Cooper, Lilliancranz, Barbat, Kelly, Potts, Carpenter, and Wells, I performed abdomino-uterectomy. A median incision was made, and the fibrous uterus lifted out of the pelvic cavity. Braided silk ligatures, which had been boiled for half an hour on each of three successive days in pure lysol, were used for the vessels in the broad ligament on each side, external to the ovaries. Clamp forceps were applied next to the uterus, which was separated from the bladder, and the ligament and vessels were divided down to the vaginal vault. Then a V-shaped incision was made anteriorly and posteriorly, beginning immediately above the vaginal attachment and extending well down into the cervix, so that when the uterus and appendages were removed there remained only a V-shaped excavation, or an anterior and a posterior lip of cervical tissue to form the pedicle. The cervical canal was thoroughly cauterized with pure liquid carbolic acid, and the flaps carefully united and the peritoneum closely attached above them with chromatized catgut, making an extra-intra peritoneal stump.

The operation was practically bloodless, as there was not a tablespoonful lost. The stump was dropped into the pelvic cavity and the abdominal incision closed with a continuous suture of catgut for the peritoneum, and silkworm for the edges of the fascia and skin. The incision was then covered with pure iodoform, and the usual gauze and cotton-wool dressings applied. No drainage was employed. The time occupied in the operation was a little over an hour. The patient made a good recovery. On November 30th, six weeks after the operation, she attended her daughter's benefit at one of our local theatres.

The tumor, as you will observe, is a diffuse fibromyoma of the uterus itself, measuring about five inches in diameter.

Case II.—Miss R——, aged forty, was sent to me by Dr. Hennessay, of Napa, Cal.

History: At the age of seventeen the patient suffered great discomfort for some days, once a month. Up to this time the catamenia had not made their visible appearance. A physician, called to attend her during one of these attacks, discovered that there was an occlusion or absence of the vagina for the lower two-thirds, and that the menstrual flow had collected in the upper patulous portion of the vagina and in the uterus. An operation was performed establishing an artificial vagina, and all went well until about ten years ago, when considerable pain recurred regularly with each menstrual epoch. For the last two or three years the catamenia have been more profuse and the pain very severe, lasting for five days to a week each month, until the patient was obliged to spend most of her time in bed. Within the last six months the menorrhagia became a metrorrhagia occurring two or three times a month. The loss of blood has at no time been very great, but the pains became more and more excruciating. In one of these attacks Dr. Hennessay was called to see her and diagnosed fibroid of the uterus.

Upon examination I advised immediate operation, because the fibroid completely filled the pelvic cavity, interfering with defecation and urination. The patient had lost flesh from 150 to 109 pounds, and the severe pain was wearing her out.

The operation was performed with the valuable assistance of Drs. McNutt, Hennessay, Flesher, Southard, Potts, and Whitehouse, on December 16, 1894. Abdomino-uterectomy was performed in the method indicated in the last case. Very little cervical tissue was left to form the stump. The peritoneal surfaces were carefully united over the uterine pedicle, and also over the ligatures in the broad ligaments. The abdominal cavity was closed without drainage and sealed with aristol and collodion, and the usual dressings applied.

The patient so far promises to make a good recovery. I believe it is of great importance to make the operation as rapidly and as bloodless as possible, as these patients are usually exsanguinated. It is also all-important to leave as little cervical tissue in the pedicle as practicable. There is no occasion for drainage and no fear of sloughing, as the vaginal vault has been undisturbed and is competent to furnish sufficient blood-supply to nourish the pedicle. It is a quicker operation than total extirpation, and has the decided advantage of leaving the vaginal vault intact and of sealing the peritoneal cavity after the operation.

Hypnotism as a Therapeutic Agent has recently received a slight impetus through the publication of a work entitled, "Die Bedeutung der hypnotischen Suggestion als Heilmittel," by Dr. Grossman, editor of the *Zeitschrift für Hypnotismus*. The author is an enthusiast on the subject, and has secured favorable opinions on hypnotism, from about thirty fairly well-known neurologists in Europe.

GREEK AS THE INTERNATIONAL LANGUAGE OF PHYSICIANS AND SCHOLARS IN GENERAL.

An Answer to my Critics and Correspondents.

By ACHILLES ROSE, M.D.,

NEW YORK.

Τίς οἶδε, ἴσως ἡμέραν τινα πραγματοποιηθῇ τὸ ὡραῖον δὶ ἡμᾶς ὄνειρον τοῦτο.—Δ. Βικέλας.

The question of adopting the living Greek of to-day as the international language of scholars, first proposed by the MEDICAL RECORD, has become the subject of much discussion. Many American and European journals, even journals printed in Turkey, have entered into the discussion. Professors of philology in German universities and colleges have found it worthy of reply, and have published their views on this subject in scientific philological periodicals—on that subject which was so warmly discussed by some of the most learned and prominent members of the New York Academy of Medicine when I read before it a paper with the above title, published in the MEDICAL RECORD of April 21, 1894.

On the whole, the responses have been favorable to our cause. The great number and the tone of the commentaries prove that thought on the subject has been aroused, and will continue. Bikélas, the Greek Washington Irving, after having read my article, wrote the words quoted at the head of this paper in regard to the idea of Greek as the universal language for scholars: "Who knows, some day, perhaps, this our beautiful dream may become reality."

I have received many congratulatory letters from physicians, from other scholars, from men of prominence and of high official positions, many urging me to continue speaking and writing on the Greek question. I feel especially gratified that all—without exception—agree that I have selected a noble cause.

The controversy was initiated by an article in our New York Greek journal Ἀτλάντις, written by an American gentleman who has mastered the Greek language. In my answer, which appeared likewise in the Ἀτλάντις, I expressed my gratitude to the author of the article for the publication of his views. They were on points of minor importance, and easy to refute. I was grateful, because I was thereby given the opportunity to complement what I had said in my paper.

The same thanks I wish to address to all my critics: I am under obligation to each and everyone for the opportunity thus afforded me of saying many more things in favor of Greek.

A German philologist, after expressing himself very courteously in praise of the energy which, he says, I have exhibited, is of the opinion that the idea of having Greek as the international language of scholars will not become realized. He refers to my narration of the failure of all attempts to invent a world-language, and also to my illustration of the attempted official invention of the Maximilian style of architecture. He says an international language for scholars can likewise neither be nominated nor invented. Resolutions to this effect might be adopted, but nobody will learn the language, because nobody has time to learn an extra language for the sole purpose of congresses and periodicals. "Dr. Rose," he says further, "is probably not sufficiently aware that the question of pronunciation does not stand now, as it stood formerly: Erasmian or Reuchlinian? but rather: When was the pronunciation of the different words transformed into the pronunciation of the Greeks of to-day? This change of pronunciation of the different sounds—as they are written—has taken place at different periods. When?—that is found by the study of inscriptions."

The small boy, when he learned in his book of natural history that the whale belonged to the class of mammalia, remarked that the whale had brought disorder into zoology. Erasmus, indeed, is the whale in philology. It is impossible to say how much disorder this man has caused during the past three hundred and sixty-five years—that is, since he introduced his absurd pronunciation.

I am not a philologist, and I do not know if researches have been made as to how German, French, and English have been pronounced in different centuries. I cannot determine whether the result of such researches would compensate for the immensity of brain work employed, but it appears to me that much time and brain-work have been wasted through the fault of Erasmus. If it had not been for him, nobody might have suggested, or might now suggest, any other pronunciation of classical Greek than the pronunciation employed by the Greeks of to-day. Whatever the scientific value of historical studies of pronunciation may be, it concerns in no way the practical study of Greek. Higher philology should only be attempted after the language has been learned practically.

It is quite true that a universal language for scholars cannot be introduced by force or by persuasion, and that nobody has time to learn an extra language for the purpose of congresses and periodicals.

It is conceded, even "im naturwissenschaftlichen Jahrhundert," as the Germans call it, that a regular and solid scholar should know Greek and Latin; it is conceded that the classics are powerful means to elevate, to ennoble our mind, our character. Since Greek is on the school plan already, there is no new language to be learned; only another, a rational method of learning has to be adopted; it has to be learned practically for practical purposes, as well as for ideal. The most perfect, the ideal language will then speak for itself, and will inspire scholars to unite in agitation for its general adoption.

Another critic says that the Greek of the newspapers and books of to-day is an artificial, a paper language, a language which nobody speaks. Still another critic, a Greek, a man of profound learning, published an extensive article on the discussion of my paper before the Academy of Medicine in the Νέα Ἡμέρα, a Greek journal of high rank. He thinks the dispute which prevails in Greece between the purists (καθαρισταί), who want to write classical Greek only, and the vulgarizers (χυδαΐσταί), who write the language which is actually spoken, will be an obstacle to the acceptation of Greek as the international language.

Some Greek newspapers employ indeed an artificial old-Greek. The Greek medical journal which I happen to read every week, the Γαληνός, is not one of them.

Dr. E. Engel has thrown an electric search-light on the prestige of the college professors of Greek with their Erasmian pronunciation; he has given no quarter in hurling sarcasm on those dignified men of science who clung to an old pedantry. He is right. But when he speaks of the artificial Greek of the journals I have to say what women say when they read Schopenhauer: "What kind has this man become acquainted with?" Dr. Engel, I am sure, has overlooked those journals which are written in the language of my Γαληνός. Here we find an idiom which is at once clear and precise, choice and of noble simplicity—language as it is really spoken, similar to English as we find it in the MEDICAL RECORD, as we hear it spoken in the Academy of Medicine. All the modern Greek books which I have read, children's stories, translations of Victor Hugo's works, above all the works of D. Bikelas, are all written in the language which is to-day spoken in Athens. I have not read any Greek medical books, but I presume they cannot be written in any other language than in the actually spoken Greek. Concerning the dispute between the purists and the vulgarizers, this is only a temporary affair between Greek writers. This dispute is not half as bad as the fashion of many German writers to mix up German with all possible

foreign words. Good modern writers in Germany as well as in Greece will continue to educate the masses to appreciate the best language, the natural, not the artificial. We, who are learning living Greek, should occupy ourselves with the best literature only.

It is most gratifying that my assertion that modern Greek does not materially differ from the ancient, has not been contested. Only one critic in the *British Medical Journal* protests, not from his own knowledge, however, but on the authority of Mr. Andrew Lang. This Mr. Lang, who said the very things which Dr. Engel says are the manifestation of a conspiracy of ignorance and malevolence against Greece. Perhaps Mr. Lang (whose profound knowledge of ancient Greek is undisputed) has actually travelled but little in Greece. He writes in that vein which is peculiar to some tourists; they delight in exaggerations of exceptional and accidental incidents, and generalize from these. To mention only one thing from which we can judge of Mr. Lang's ill-humor: He finds in the modern Greek "stereotyped phrases most distasteful to the scholar." Sure enough, he could have found such phrases at home, and everywhere. Everywhere scholarly speaking and writing are the exception, the commonplace is the rule. But wise Mirza Shaffy has said, "I will praise God that not all men are wise, because if they were, wisdom would be too cheap."

What I have to say here in regard to the differences between old and new Greek, I shall include in my answer to several colleagues who wrote to me asking about the best method of learning living Greek.

I have just been reading for the first time Dr. E. Engel's book, "Griechische Frühlingstage," and have been pleasantly surprised to find the following instruction: "How shall we learn the real language of the New Greeks? Turn over the leaves of one of the many grammars to read something about pronunciation, but then throw it, and leave it, aside, and take instead a collection of Greek popular songs and fairy tales. Finally read comedies which really have been played." I myself had followed a similar course when I undertook to learn the living Greek, and I gave some of my correspondents the advice to do likewise. I recommend the reading of children's stories, above all of Bikélas's beautiful Greek translation of "Andersen's Fairy Tales." The most essential, however, is to speak with Greeks and hear Greeks speak among themselves. In a little circular by means of which I hope to excite interest in the establishment of a Greek school, I say: Let us do away with the study of Greek by the eye only! Let us have a Greek school here in New York, with natives of Greece as teachers, with children of immigrated Greeks, with Greek as the language of the house, where our own children can learn Greek, just as they can learn French or German in French and German schools in this, our city.

Dr. Engel says, "Whoever has learned old Greek will need not much more than to learn some additional few hundred new words. This is rather easy work, since the roots of these words are Old-Greek." He says further, that a foreigner of classical education thus prepared will understand the Greeks in Greece, and the Greeks will understand him, provided he have the right pronunciation.

To this one might say: there exists in reality no New-Greek. The words which deviate from the literary language of the classical period are at least as old as the words of the same meaning in the classics, although we cannot find them in our school dictionary. κρασί (wine), νερόν (water), are beautiful words of the oldest Greek, perhaps older than οἶνος and ὕδωρ; the college dictionary does not know them.

Dr. Koumanoudes, a professor at the Athens University, has collected from inscriptions and other sources ten thousand Greek words not met with in any Greek text of the classical period. My Greek friends tell me that words and forms of speech used in Homer and some of the earlier poets, which in later classical writers have disappeared, are in constant use at the present day among the people in different parts of Greece.

Only what is dead, like the Latin language, does not change any more. Greek has changed from age to age, like every living language, because it has continued to live, but as Mr. Gennadios, in a famous article on Greek, which appeared in the *Forum*, October, 1894, and which has caused a flood of controversies, commentaries, and enthusiastic approvals, says of the Greek language, "plus ça change, plus c'est la même chose." Greek was always itself and itself alone. Greek has never made a compromise with any other language. The difference now remaining between old and modern Greek is that difference which exists between old and modern generally. Thus it has been the unique destiny of the Greek language to have had, from prehistoric times down to our own, an unbroken life. Not one link is wanting in this chain which binds the new Greek to the old. Of course the classic texts, except when they gave—as in Aristophanes—the popular idiom, differed from the everyday peoples' language just as well as the classic texts in other languages differ from the idiom of the people in their daily intercourse. But the classical and the popular language are Greek, one just as much as the other. The Greek which I speak with my Greek friends in the καφενεῖον or in the παντοπουλειόν in Roosevelt Street in this city of New York is not a iota less Greek as the Greek of the classical writers.

The methods of learning Greek or any language which Dr. Engel, myself, and perhaps many more, have discovered for ourselves instinctively, is really pointed out as being unmistakably the best when we consider certain facts of physiological anatomy and pathology of the brain. From the ways in which the use of the language is lost, or suffers varying degrees and kinds of impairment, we can learn how it best may be acquired. Monographs, above all Kussmaul's philosophical and elaborate work on the disturbance of speech, numerous articles in our medical periodicals, and special chapters in our text-books on nervous diseases, treat on the defects of speech in their relation to neuropathology. The first to apply the recent discoveries in this direction to the methods of learning and teaching languages, was Dr. Howel T. Pershing. He has expounded his views in an article entitled "Language and Brain Disease," appearing in the *Popular Science Monthly* for October, 1892.

I may be permitted to give an abstract of this most valuable paper: All the motions and sensations of the various parts of the body have their centres in the brain. Four centres are especially concerned in the use of language; the auditory centre, by which words are heard; the motor speech centre, which excites and controls the vocal organs in speaking; the visual centre, by which the written words are seen; and the writing centre, which guides the motions of the hand in writing. The centres are capable of individual development by practice. Certain pathological conditions instruct us on the relative importance of each of these centres in the different ways of using language. The loss occasioned by the destruction of any language centre is an indication of the defect that must result from neglecting to cultivate the same centre by practice. When the auditory centre is aroused by impulses coming from the ears, we have the sensation of sound; when it is aroused by nerve-currents, not from the ears but from other parts of the brain, we have only the memory of sound. For a word to be understood, the auditory centre alone is not sufficient. The sound must awaken the memories of other sensations. The nerve-currents passing from one centre to another are called association impulses. Prompt and strong associations must be cultivated as a means of securing clear and vivid ideas. The auditory centre is the first lan-

guage centre to be developed. A child first hears, then understands the sound of a few words, then it imitates the sounds it understands, and soon can use them. Here we have the co-operation of the motor speech centre. The two centres work and develop together, but the auditory centre is the more independent and fundamental. If a child becomes deaf, even as late as the tenth or eleventh year, it also becomes mute, unless special educational measures are employed; in adults destruction of the auditory centre interferes sadly with talking, while destruction of the motor speech centre does not seem to interfere at all with the understanding of speech. When reading is first undertaken, the auditory and motor speech centres, with their association fibres, are already well developed. The visual centre now begins to work with them. At first it is necessary to read aloud in order to make the association impulses exact and vigorous. In writing, the visual memory may be an aid to correct spelling. Disease cutting off the communication of the visual centres with other centres causes mind-blindness. The patient sees but does not recognize what he sees. If the affection is so slight that he can still recognize ordinary objects, but not written or printed words, he is only word-blind. Although reading in such a case is impossible, writing is not prevented; the patient, however, cannot read what he has just written. Speaking and the understanding of speech are not interfered with at all. Destruction of the motor speech centre causes a much more extensive interference with the use of language; the motions of the vocal organs being no longer co-ordinated, an inarticulate jargon, or the senseless repetition of a word or phrase, is all that is left of the power of speech. The ability to write is also lost. Reading aloud is, of course, impossible; but it is also a matter of common observation in such cases, that the ability to understand print is lost or greatly impaired. This proves that in most persons direct associations between visual words and ideas, if they exist at all, are too weak to be depended upon.

It is the destruction of the auditory centre which causes the most extensive loss of language. In such pathological conditions in which words are heard but not understood, we speak of word deafness. There are other pathological conditions in which, although the vocal apparatus is in perfect order, the words uttered are mutilated, deformed, and often totally different from the ones intended. We learn here that in talking the most important association impulses do not go directly from the centres for ideas to the motor speech centre, but to the auditory centre, which, remembering the sounds, by fresh impulses arouses the motor centre to utter them. Writing is still more interfered with, because it depends upon the utterance-memory, which goes astray without the sound-memory.

The auditory centre is essential to the understanding of what is read. In reading the visual centre cannot, as a rule, call up the ideas, else destruction of the motor speech centre would not interfere with reading as it does. Nor is the motor speech centre directly connected with the centres for ideas; if it were, destruction of the auditory centre would not interfere with talking as it does. This leaves only the auditory centre, which is abundantly capable, for the sounds of the words readily awaken ideas before the other language centres begin to work and after they have been destroyed. The auditory centre is the central station, through which the other language centres communicate with the centres for ideas. The sound of a word is the word itself. Printed words are only convenient symbols for recalling the sounds. Thinking requires the use of words, not visual words, but the words heard and uttered. It is true deaf-mutes may learn to read and even to speak, and doubtless to use visual words in thinking; but it is with much more than ordinary difficulty. It is a fact of great significance that those deaf-mutes who have once been able to hear, have a great advantage over those deaf from birth, not only in learning to read and speak, but in general mental capacity.

Let us apply the above facts to the method of learning another language than our own. There is the prevailing school and college method to learn the language by force of memory from grammar and dictionary. By this method it is conceded that the ability to converse is not acquired, but it has been generally assumed that by it the pupil could at least learn to read, and perhaps, if diligent, to write to advantage. Yet, even for this purpose alone, the grammatical method must be a failure in so far as it neglects to train the pupil to a quick perception and a ready utterance of the sounds of the language, for we have seen that the auditory and motor speech centres do an essential part of the work in reading and writing. Even if direct associations from the visual centre may be cultivated, as in the case of deaf-mutes, why, instead of an easy and natural method, choose an unnatural and difficult one that leads to poor results? What are the results of the grammatical instruction? The vast majority of our college graduates neglect to read the ancient authors. They are not able to read them, but only to make a translation. They find no sufficient reward for this slow and irksome process.

Dr. Engel, while travelling in Greece, one day visited a school, and was delighted to observe with how much facility the boys read Demosthenes and Homer. He was asked to read before the class some Greek verses with the pronunciation as employed in German colleges. The Greek boys, while he was reading from the Ilias, did not know what to say at first, as they were under the impression he was reading German; but when they were given to understand that it should represent Greek, they burst out into laughter, stamping with their feet, screaming and uttering cat-calls, and the principal himself could not help joining in the general hilarity. Anyone can try the experiment of creating fun among Greeks if he speaks to them of Erasmus of Rotterdam.

We can easily understand this hilarity when we learn from Hamerton, quoted by Dr. Pershing, how a Frenchman, who had long studied English and was thoroughly conversant with the literature, but had never become really familiar with English sound, read Tennyson's "Claribel:"

"At ev ze bittle bommess
Azvart ze zeeket lon
At none ze veeld be ommess
Aboot ze most edston
At meedneeg ze mon commess
An lokez doon alon
Ere songg ze lintveet svelless
Ze clirvoiced mari dvelless
Ze slombroos var ootvelless
Ze babblang ronnel creepess
Ze ollor grot replee-ess
Vere Claribel lovlee-ess."

Now the student, like this Frenchman, having reached the stage of progress here indicated, visits our country whose language he has been reading. What he hears at first is almost wholly unintelligible, though the same words in print would be familiar. A little later it is not uncommon for him to hear a sentence without comprehending it at all, when suddenly it will flash upon his mind as though he had seen in print what he is hearing and as if he had pronounced it himself, and then he understands readily. The same thing occurs in listening to one's native tongue when the auditory centre has been slightly damaged by disease. When the student becomes familiar with the spoken language through every-day experience, he reads faster, finding a clearness and vigor of meaning before unknown. It is not because his vocabulary is larger, but because it is more efficient. The auditory centre, which formerly, through lack of practice, failed to perform an essential part of the work, is now, at the

suggestion of the visual centre, quick to recall each sound, and, reinforced by the utterance-memory, is quick, accurate, and vigorous in reviving each idea. The work of exchange is now done by the true coin of the realm.

Greece, the life and customs, the virtues and faults of the Greek people are little known. Those tourists who have visited the Greek seaports, or who have lived in Athens only, do not know the country people, those Greeks of the interior of the land or of the islands, who are the heart of the Greek nation and true types of Greek character.

The nation which, after more than one thousand eight hundred years of bondage under different conquerors, the last time under Turkish yoke during almost four hundred years, fought with fire and sword, alone, without foreign help, without allies, and gained, through its heroism, liberty, freedom, independence, this nation deserves our admiration. It is impossible to find in all history more bravery, more patriotism than in the history of the rising against the Turks, in the seven years' war from 1821 to 1827. Only the historians of the classical period are wanting as yet to do justice to the war of the greatest horrors and the greatest bravery.

Several of my German correspondents write that the Greeks at present have alienated German sympathies for a long time, on account of financial failures of the Greek Government, by which failures a great many Germans have lost their money. They say that this condition of things may much interfere with the success of an agitation for the adoption of the Greek language.

In answer to these correspondents I may be allowed to give the words of a Greek, as Dr. Engel has reported them. The Greek said: "You know that I have studied philology and archæology, and that I feel at least as enthusiastic about Old Hellas as you German philologists. Shall I tell you my true opinion from my heart? We New-Greeks, with all our weaknesses and faults, with our haste, and at the same time with our oriental slowness, we are much better than the Old-Greeks.

"Please let me finish! Yes, better as citizens of our state, better as sons of our fatherland, better as members of human society. One thing I admit: the Parthenon is more beautiful than the Metropolitan Church in the Phokion Street; the Hermes of Praxiteles is more beautiful than its plaster cast in the Exchange of Athens; Sophokles is a greater poet than Mr. Koromilas, and Thukydides is a greater historian than the elder Trikoupis, although the latter's history of the war for liberty (the rising against the Turks) is not bad. In fact, in regard to art we New-Greeks are a poor shadow of what our ancestors have been.

"On the other hand: With fire and sword have we taken what our glorious forefathers never possessed, one common fatherland. Nowhere and at no time had they a united Greece; treason and trickery, brethren fighting everywhere during the whole lauded period of old Grecian history. The old history may be all well enough for the schools to read and to make compositions upon; we New-Greek men need better examples, and, glory be to God, we find them in the history of the New-Greek war for liberty. We possess a united beloved fatherland, whose sons stand shoulder to shoulder against the oppressor of our brethren. Where was there ever a Greek army like ours in Thessaly? There we find no more Athen's hegemony, and Sparta's Peloponesian confederacy; it is all over with Corinth's envy and Thebes's trickery. What Demosthenes could not accomplish—to call all Greece together against the common enemy in the North—with us this will be accomplished by only one order from one government. We shall no more give to the world either a Parthenon or a Hermes, but we shall never again, through the fault of our own discord, become bent under the heel of the Barbarian.

"Our financial trouble? How smart you are, you Europeans! You judge from the quotations of our securities on 'Change. The Greek loans are down, but what has this to do with the wealth of a land? Our government has no money, but the inhabitants have money or other property. There exists no pauperism and there are no proletarians among us, and this is worth more than the quotation at par of our loans.

"We poor? If Turkey would offer to sell us Epiros, Macedonia, and Creta for one milliard drachmas, in one month the money would be raised. No king could buy for one milliard the most miserable of our islands.

"We have a fatherland, and we love it. All people love theirs; not all with the same fervor as we. At home and abroad, Hellas above all! Have you ever heard in our times that Greeks in foreign lands have become untrue to their country? Do you know who gave us the most beautiful buildings in Athens? Greeks in foreign lands. An old Greek, Theognis, long ago sang: 'Many countries have I seen, and I was pleased with some, but there exists nothing sweeter than our own.' The severest punishment of the old Greeks was exile. Do you know what is the greatest curse which a Greek, when in passion, casts at another Greek? 'May you be buried in foreign soil!' And when anywhere two Greeks meet in foreign land, with which salutation do they part? Καλὴν πατρίδα (Happy fatherland, meaning, may you return happy to our fatherland).

"We are *one* united people, we all speak *one* language, we all pray to *one* God, we have all *one* and the same will, the will to live as a nation, and we shall live!"

I may be allowed to quote from another article—not yet published—of my friend, Dr. Καζαντζῆς. "Our civilization, as it stands, is thoroughly impregnated with Greek ideas. Our arts, our letters, our morals, our institutions, our religious tendencies even—since it is no longer permissible to regard monotheism as an entirely Jewish legacy—are based upon Greek culture, inspired by Greek perfection, and renovated with Greek refinement. The study of Greek is not, as it has been heretofore, a mere linguistic discipline, or a purely scholarly attainment, but it means a practical study of the sources and origins of our modern civilization. It affords to the modern mind a better comprehension of the nature and character of our own elements of culture. For this purpose the methods and systems of teaching and learning Greek must be remodelled. Grammatical chicane has to be reduced to a more human minimum; a closer attention to the spirit must be advanced to a really humanistic maximum."

Greek, the most beautiful of languages, will live

ΤΟ ΩΡΑΙΟΝ ΖΗ ΑΙΩΝΙΩΣ!

Decrease of American Students in German Laboratories.—A correspondent of the *Occidental Medical Times* writes from Berlin: "When I worked in Professor Arnold's laboratory in Heidelberg, ten years ago, it was known as the 'American Laboratory.' At that time the Americans frequently exceeded the Germans in numbers, and Heidelberg always has been a favorite rendezvous for American physicians. In a conversation with Professor Arnold a few weeks ago, he assured me that the number of American physicians who did work in pathological anatomy at his laboratory was diminishing each year. This falling off in attendance he attributed to the improved facilities for such instruction in the United States. 'When the professors of such branches as anatomy, physiology, and pathology,' said he, 'can devote themselves solely to their respective subjects, the pre-eminence of American medicine will be assured.'"

THE WORK OF THE ACADEMY OF MEDICINE.

Being an Address by the Retiring President, Thursday Evening, January 17, 1895.

By D. B. St. JOHN ROOSA, M.D., LL.D.,

NEW YORK.

Fellows of the New York Academy of Medicine, Gentlemen: Two years ago, by virtue of your favor and choice, I assumed the office of President of this Academy. Since that time, thirty-four regular meetings have been held, including the one at which we are now assembled, and seven special meetings. It has been my privilege to attend all of the regular meetings, and to be present throughout their proceedings, in all instances except two, where I was obliged to absent myself after the session was opened. Of the special meetings, I have been present at all but one. I allude to these in themselves unimportant details, because they furnish, if rightly considered, a broad view of the general public work of the Academy, and, although they can give no idea of the various meetings in which your executive officers are gathered together to consider the machinery which enables the Institution to carry on its work; nor do these facts include the important matters of the various sections, comprising the whole domain of medicine and surgery, into which the Academy is now divided. But the public gatherings of the whole Academy furnish a course of medical instruction which, from practical experience, I am able thoroughly to appreciate. It has been a course of well-considered lectures from experts and authorities on the different topics which they have discussed, and added to this, in most instances, we have also enjoyed the criticisms and suggestions of those doctors equally expert with the author of the paper. These papers, with the exception of one from Washington, two from Buffalo, and one from Albany, have been by the Resident Fellows of the Academy. If there ever is danger to any specialist that he tread too closely the narrow track of his own path, such a course as that which I have had the honor of attending, would serve him in good stead to keep him from a circumscribed and cloudy view. I congratulate the Academy on the record it has made in these scientific productions, and in the work of these special meetings. Although we have not succeeded in accomplishing all that we desire, either in the direction of National Quarantine, or improvement of the water-shed, and the consequent purification of the water-supply, we have performed a fundamental work upon which a future edifice of progress will be erected. We have turned public opinion in the profession to these important subjects—in the former case, the opinion of the profession throughout the country; and while in the latter, perhaps, the subject does not invite so large a view, we have here stimulated inquiry in a proper way among the profession in this city and State. We have demonstrated the absurdity of trying to purify the water-supply of a city by taking possession of the land lying upon the rivers which furnish it. Besides all this, by your action in respect to both these matters, you have vindicated the right of the Academy to be something more than a mere academic debating club, discussing strictly hygienic and therapeutic questions, without looking for any practical outcome as a result of the debates.

Under the direction of the Council, I appointed a committee to look after the interests of Medical Legislation in the Constitutional Convention. This committee, consisting of Drs. Daniel Lewis, Fox, and Pryor, did excellent work, the chief of which fell upon Dr. Pryor, as Secretary of the Committee. He visited Albany, attended several sessions of the convention, and so impressed committees having matters pertaining to our work in the State in charge, that a substantial advance was made. It is now possible to secure appropriate legislation in the Coroners' system, and in other affairs of which their report speaks very fully. It is seen that the Committee was fully alive to the importance of the work entrusted to it. The unanswerable argument, to those who object to bodies like ours undertaking to exercise an influence in higher politics, is that, unless we do, individuals, acting upon their own responsibility, will achieve very much in politics of a lower order. The Academy of Medicine, as I ventured to state in my inaugural address, is not, like the Academy of Medicine of Paris, a collection of mere savants, but it is a body of practical physicians and surgeons, who are obliged, in the absence of State arrangements for medical affairs, to attend to these matters themselves.

In my opinion, the Council of the Academy ought to keep a very strict watch of proposed legislation in Albany, affecting the health of the State, and interfere, as a body, when that is threatened by improper bills, of which it is intended to make laws. The majority, and, I trust, a very large majority of the Fellows of the Academy, believe that, in a broad and catholic way, we should stand between the community and the government, to assist and direct them in all legislation that may affect the public health. This is the only medical body in this city which can at all adequately perform this work, for the simple reason that the term of office of the executive officers is long enough to allow plans to be made and carried on, without interruption or haste, for a reasonable period of time.

During these two years an attempt was honestly made to convert the beautiful rooms on the lower floor to club purposes, for the benefit, solely, of the Fellows, that they might cultivate the social amenities with each other, when not engaged in the meetings of the Academy, the sections, or the committees. This attempt has not been entirely successful, but I believe the good judgment of the Academy will finally evolve a way in which the smoking-room and dining-room may have a larger use than that to be obtained immediately after the stated meetings, and that a wider acquaintance among the members will there be cultivated.

During the last year the library has been enlarged by the accession of four thousand volumes and two thousand five hundred pamphlets, making a total number of fifty-one thousand volumes; and the space for the library has been increased to such an extent, that we may believe that it will be sufficient for the uses of the Academy for the next decade or two, unless the generosity of our fellow-citizens and of the Academicians may be so great as to exceed our present ideas. The Academy deserves the largest medical library in the United States. New York, whatever may be thought of Washington and other centres, is the place where such a library will accomplish the most, where it would be the most accessible to the largest number of workers; and, I have no doubt that a future President will inform you that that end has been accomplished, and that the greatest reference library in this country is to be found within our walls.

A minor improvement, that has occurred during the past two years, is the establishment of our own plant for the generation of electric light, so that the expense of lighting our building will be notably decreased.

The formation of the Bureau for Nurses, and its successful establishment during the past year, is a feature for which the Fellows are, I am sure, grateful, and which they will desire to amplify and sustain in every possible way. For the success of this bureau we are indebted to a very able committee, of which Dr. Landon Carter Gray has been Chairman.

During my term, a law has been passed by the Legislature of the State of New York, which exempts such institutions as ours from taxation. This, certainly, the State ought to have done long ago, and not have com-

pelled the Academy to make certain regulations in regard to a public library before it could be exempt from taxation. The work of this Academy is actually work for the State and the community. There are no private interests to be served here, and I have no doubt, unless taxation is made general on every church, hospital, reformatory, and similar institution of the country, that this righteous law will never be repealed. I took a very great interest in helping to originate the movement, which finally ended in this general bill, and, in conjunction with members of the legal profession and managers of certain benevolent institutions, assisted to the extent of my ability in carrying the work through.

On my accession to the presidency, there were seven hundred and fifty-two Resident Fellows, thirty-two Non-resident Fellows, forty-two Corresponding Fellows, and nine Honorary Fellows, being a total of eight hundred and thirty-five. At the close of my term, in 1895, there are seven hundred and seventy-four Resident Fellows, sixty Non-resident Fellows, forty Corresponding Fellows, and seven Honorary Fellows, making a total of eight hundred and eighty-one, being an increase in the whole number of forty-six. The annual report of the Treasurer, printed and circulated, with the notices for the annual meeting, for the benefit of the Academy, for the first time after my term of office began, in the year 1894, again renewed this year, gives you an accurate idea of the Academy's financial condition, which is thoroughly sound, although, we may hope, when the present period of commercial distress is fully recovered from, that the gifts of generous men, who appreciate our work, will make it much better. This period has been so severe, that young members of the profession, fully eligible, whom we should have been glad to welcome, have hesitated about incurring the obligation of the admission fee and the annual dues. It is a matter of pleasant surprise to me that we have decidedly increased in our resident fellowship, in spite of the difficulties induced by the stringency in the money market. But, I have no doubt, more prosperous times will also bring prosperity in fuller measure to a profession which, although it serves the public very largely, without honorarium or fee, is among the first to suffer from any general financial depression.

At this point I think we have a right to indulge in a little self-congratulation over the business capacity of members of the medical profession. It is sometimes asserted, and perhaps believed, that our profession has no aptitude for business affairs. I have always thought that our apparent want of business skill for private matters was simply a want of attention, generally enforced by the exactions of professional life, to the details that are necessary to make business thriving — in other words, a man usually has no time to practise medicine and to also make money; but that a man with intelligence and education enough to make a good doctor, would generally make a good business man, did he attempt it, I feel morally sure. At any rate, let us look at the facts in regard to the business outcome of the labors of the founders, and benefactors, and previous officers of the New York Academy of Medicine. We are now, after a period of forty-eight years, in a commodious, fire-proof building of our own, which cost, in round numbers, about $375.000, in the heart of a beautiful part of the city, having begun in a very humble room, in an insignificant building, in an obscure quarter of the town, with no library and no funds. We own all the furniture, and the library, which, of course, has a value not easily estimated, and we owe at this moment, say, in round numbers, $13,000. If any of our business gentlemen, or artists, or lawyers, choose to make a comparison with the condition of their club-houses, or institutions devoted to professional work alone, I am sure we shall not shrink from it. The capacity of physicians to govern hospitals was demonstrated by the Medical Corps of the United States Army and Navy during the Civil War. Never were hospitals better managed, and in them none but doctors had a voice. The present financial condition of our Academy is a proof that this aptitude for business affairs extends to such an institution as this. We may, I think, invite the most careful investigations of our financial methods, without any fear as to the results of the examination.

These statements I think pretty accurately represent the work of the Academy during the past two years, as far as it can be represented by statistics and figures. The spirit and aims of the Academy, during that period, whether they have been of a high order and worthy of the profession which it represents, it must be for your judgment to determine. Certainly, it will be a matter of most profound regret to the one who now gives up the position, which he has held during that period, if it should be your conclusion that, in any manner, the aims of those who have founded and maintained this institution, in a broad spirit, shall not have been respected and amplified, so far as changed conditions rendered this possible.

The Academy is no longer a small body of physicians, in a provincial town, but it is composed of nearly a thousand members, in a metropolis which is becoming justly celebrated for the achievements of its Fellows in medical science and art. We may claim for New York that it is one of the medical centres of the world, fast assuming an importance which may cause it to be placed on the same plane with those that have existed for centuries in the Old World, and it may be said to represent that large body of men and women called the medical profession of the city.

I have been greatly honored by the suggestions made by various Fellows of the Academy, whose opinion I highly regard, and by the nomination, made in open meeting by one of the Trustees, that I should again become a candidate for your suffrages. But, from the moment that I received the news that I had been elected until now, I have never changed my purpose—not to seek a re-election at your hands. There may have been times in which, during the formation of the Academy and, especially, in the erection of the new building and preparations for it, when it was wise to secure the services of a president for two or more continuous terms, from among the eminent men whom you have elected to preside over your deliberations. But that period has passed. The honor, in my judgment, of being President of the Academy, is very great—second to none that can be obtained by a member of the profession, perhaps, in this country. As such, it is worthy of most grateful acceptance when conferred, but it is an honor that ought to be distributed during a decade, at least, the number of times allowed by each president, having but one term. No good purpose can now, in my opinion, be gained by two continuous terms. The period of service is long enough to allow of the maturing and development of plans, if the President has any, for the building-up of the Academy, and if such an officer be sustained by the Council and Trustees.

Before I turn to welcome my successor, and to hand to him the insignia of office, there are one or two minor points, in the way of changes in our management, which I would respectfully propose for your consideration. I am very well aware that the views of a retiring president cannot have the importance of those of his successor, and yet there may be a little value attached to the experience of one who has been your chief servant for two years. In my judgment, it would be of great service to the Academy, if the offices of Treasurer and Treasurer of the Board of Trustees, were merged in one. The present system produces an unnecessary want of clearness in the statement of accounts, and diminishes the working capacity of both the Council and the Trustees. The Academy should also ask the Legislature for an amendment to its charter, in order that it may have the power to hold

more property than is at present conferred ; and, in general terms, I may say that I believe the present Constitution and By-laws, in a few instances, have been outgrown, and need modification and simplification.

The Academy has chosen for its new president a gentleman well known to the profession in this city and country. He has held high executive positions, and entirely to the satisfaction of the profession. He is in the flower of life, in the full vigor of manhood, and, I believe, adequately represents the desire of this Academy to become a great power in conserving the health of the commonwealth, and in advancing the scientific knowledge of our profession. For the past year, as Vice-President, he has, by his regular attendance at the meetings of the Council, come into very close relations with the governing body, has thoroughly learned the workings of the Academy, and is in full sympathy with its aims. I congratulate the profession on his accession to the position, and I predict for him a most useful period of service, which will always be gratefully remembered.

And now, thanking you for the consideration which has been extended to me, as I have endeavored to do my duty in this office, I turn to my successor with interest and pride.

Progress of Medical Science.

Statistics of Renal Surgery.—A paper has recently been published by Dr. James Israel, giving the results of 81 capital operations on the kidney performed by him during the past eleven years, with a mortality of 13.7 per cent. Of these operations 37 were nephrectomies, of which six were fatal. This result is exceptionally favorable, as compared with the results obtained by other surgeons. Thus, of the 100 cases collected by Barth in 1892, 62 either died from the operation or from metastases or intercurrent troubles. (*The Boston Medical and Surgical Journal.*) In 19 of Israel's cases, the kidney was extirpated for hydronephrosis, for pyonephrosis, and abscess of the kidney ; four of these patients (twenty-one per cent.) died. The nine patients suffering from hydronephrosis all got well. In 12 cases, the extirpation was performed for malignant growths. Only two of these patients died. Israel attributes this small mortality less to the skill of the operator than to improvement in the means of diagnosis, which enables the surgeon to distinguish renal tumors from divers other abdominal growths, and thus perform ablation of the kidney without opening the peritoneum. Moreover, the greater precision in diagnosis obtained by the surgeon enables him to operate earlier, when the tumor is still small, and has not acquired attachment to surrounding parts. Thus, in two cases, the tumor, which had not exceeded the size of a cherry, had been recognized by palpation while the patient, lying on the sound side, was taking a deep breath. Tumors of the liver coming down in front of the kidney may be a cause of mistaken diagnosis. Thus, in one case, the author found at the operation, instead of the supposed renal tumor, a tumor the size of the two fists descending from the lower surface of the liver. He promptly closed up the wound. In another case, a young girl of fifteen, he found, instead of a renal tumor, an angio-sarcoma of the liver, which was removed with success.

Apart from the data afforded by palpation and the detection of particles of the neoplasm in the urine—even when the bladder is found intact by the cystoscope—there exists no certain sign of malignant tumor of the kidney. It cannot even be said that the type of the hæmaturia is characteristic. Israel suggests as of some value, a diagnostic method which consists in plunging the needle of a Pravaz syringe into the substance of the tumor and obtaining by suction a little of its contents. In three cases he has succeeded in thus removing enough of the tissue elements to enable him to make a diagnosis of the neoplasm. A second cause of lessened mortality in nephrectomy operations is the exclusive employment of the extra-peritoneal method. It is in this way that Israel has removed all the tumors of the kidney—even the most voluminous—on which he has been called to operate. There need be no fear in making a large incision, transverse or oblique, curved or angular. The kidney should first be separated from the fat in which it is embedded, then lifted up, tied off, and removed ; then by the aid of long retractors, with large blade and polished so as to reflect the light, the retro-peritoneal space is brought well into view, so that all bleeding can be stopped and any accidental perforations of the peritoneum sutured. Lastly, the wound is drained—not packed—and closed with silk sutures.

In one of Israel's fatal cases, symptoms of iodoform poisoning set in, to which he attributes the death. Since then he has abandoned the use of antiseptics in dressings of the abdominal wound. In another case where a cancer of the right kidney was extirpated, the patient, a feeble and cachectic woman, was kept under chloroform two hours ; she died at the end of forty hours, and at the autopsy there was found recent cloudy swelling of the parenchyma of the left kidney, which the author considered as the cause of death. This alteration, he says, can only be explained by the toxic action of chloroform on a person already greatly enfeebled. He has since investigated the action of chloroform on the kidneys. In seventeen cases of extirpation of one kidney, he found in fourteen signs of a slight affection of the other kidney after the operation. This affection is generally of short duration. In a patient who underwent an operation for cysto-sarcoma, he observed a transient albuminuria. Six months later, this same patient underwent another surgical operation, and again for several days albumin and casts were found in the urine. These facts seem to demonstrate the noxious action of chloroform on the renal epithelium.

A very interesting case of ureteritis was observed by Israel in an adult man affected for eight years with severe attacks of renal colic on the left side. The diagnosis of renal calculus was made. February 10, 1893, an incision was made over the kidney, which was exposed from the convexity to the hilum, but no calculus was found. As the sufferings of the patient were aggravated instead of benefited by the operation, two months afterward a long incision was made in the same region, and the ureter was laid bare in its whole length. It was found indurated and very much thickened ; and at least three times the normal diameter. By an incision in the pelvis, a No. 10 bougie was easily passed down to the bladder. This opening was not closed, in hope that the free flow of urine by the wound would put an end to the sufferings of the patient. This was not the case, and a few days later it was decided to perform ablation of the kidney, which presented to a notable degree the alterations of hydronephrosis by retention. The patient made a speedy recovery, and has been entirely relieved of his pains. Israel explains the obstinate and continuous renal colics in this case by the fact that the ureter was converted into a rigid tube by the chronic inflammation, and could no longer expel the urine by its periodical and forcible contractions. There was, hence, stasis of urine and elevation of pressure, sufficient to cause colics.

Nephrectomy was practised in four cases of renal tuberculosis. One of the patients died soon after of tuberculous meningitis ; the others survived the operation and have kept well to the present time. In two cases of renal syphilis nephrectomy was performed with success. In three cases of urinary calculus attended with aneuria, the operation of nephrolithotomy was performed. Two of these patients died, the operation

having been too long delayed; in fact, to be successful, the lithotomy ought to be practised early, at least within forty-eight hours of the onset of the aneuria. In the patient that survived, the secretion of the right kidney was resumed immediately after the removal of the left kidney. This fact seems to indicate the possibility of a reflex aneuria by arrest of the secretion of a kidney, by reason of occlusion by a calculus of the ureter of the other kidney. The author has also seen the irritation of the pedicle of an extirpated kidney produce an arrest of the secretion of the other kidney. A drainage-tube had caused this irritation; when this was removed, the quantity of urine increased from 500 to 2,000 c.c., with cessation of the pain which before had existed at the site of the operation.

In cases of floating kidney, Israel is on general principles opposed to operative interference. He does not believe that the symptoms observed are, in general, the consequence of the abnormal mobility of the kidney. Often the physician has to do with women that are nervous or present some affection of the genital organs. Others have enteroptosis, and it is the relaxation, the fall of the viscera, which is the cause of the functional troubles, rather than the floating kidney. Moreover, we often observe hysterical nephralgias when the kidney is normally situated; also many women present no symptom although one of the kidneys is mobile. Lastly, by an appropriate treatment, we may sometimes cause disappearance of the symptoms wrongly attributed to renal ectopia; and on the whole it may be affirmed that the medical treatment of this affection is much more important than any local treatment.

Nevertheless, nephropexy has its indications, as when the surgeon finds himself in presence of a case of floating kidney accompanied by those paroxysms of renal pain which are the prodrome of intermittent hydronephrosis. Likewise, he will have recourse to nephropexy when the patient complains of continuous pains which seem certainly due to displacement of the kidney, and which resist all medical treatment.

Parasitism, Symbiosis, and Commensalism.—When one organism lives in or upon another, and feeds at that other's expense, as an unbidden guest, without benefiting its host in any way, we call the condition parasitism. But there are many cases where the two beings form a physiological partnership, and these are generally included under the name symbiosis. The members of the firm may be both animals, or both plants, or one may be an animal and the other a plant. In some the association is so close that it is exceedingly difficult to determine that they are indeed two beings and not one. For many years, for example, in some radiolarians little yellow bodies had been noticed. They were seen to possess a well-defined nucleus and a cell-wall, and they were looked upon at one time as spores, at another as secretory cells; but later it was found that, though the radiolarian might die, yet the yellow bodies would survive and multiply. They were, in fact, minute algæ, and, though they lived in the radiolarian, the host and the guests both prospered; for the host gave off carbonic acid and nitrogeneous products, which formed the best food for his guests, the algæ; and these in their turn evolved oxygen, and so supplied one of the chief wants of the radiolarian. Each profited by the association. In other cases the union is much less intimate, and these have been differentiated by name under the term Commensalism. There is a hermit crab, who carries about with him attached to his shell, or even to his claw, a sea-anemone. When the crab feeds the anemone shares the feast, and, moreover, enjoys the benefits of free locomotion, though little able to move itself. In its turn it serves to protect the crab by hiding him, and may also aid in killing or numbing his prey; and when the time comes that the crab must seek a new shell, he carefully assists his partner to change his home, also showing how greatly he appreciates the union. To other examples of this sort of partnership we have referred elsewhere in an account of the additions which have been made to the museum of the Royal College of Surgeons of England during the past year. An acacia tree finds itself in danger of destruction by ants and other insects, and enlists in its service a tribe of ants, who are not only innocuous, but ready to fight for the plant and keep off its foes. But the ants are true mercenaries, and will not serve without pay, and for them the tree provides food and shelter—hollow appendages (stipules) to live in, and nutrient fluids on which they may feed. Then, when the foes appear, they rush out and drive them off. The allied phenomena of parasitism, symbiosis, and commensalism illustrate in a marked manner the interdependence of organisms, and bring home to us in a picturesque manner the fact that few are able to live only for and by themselves, but that it is the common lot by serving others to serve ourselves.—*The Lancet.*

Herniotomy for Strangulation in Infants.—Notwithstanding the very rare occurrence of herniotomy on an infant in the practice of any single surgeon, Dr. Stern has been able to add to a collection of 99 such cases, made by Knobloch in 1890, no fewer than 54 fresh cases taken from journals and hospital reports. Of the total number, 138 were cases of inguinal, and 14 cases of umbilical hernia. The remaining case was one of femoral hernia. In 110 cases the patient's age was under twelve months. The mortality in the cases of operation for strangulated inguinal hernia was about twenty-eight per cent. The two tables taken together show that the mortality after operation for this form of hernia has, since the introduction of the antiseptic method, been reduced from thirty-three to about twenty-one per cent. The latter proportion, however, is regarded by Stern as too high, since in some cases the death could not be attributed to the results either of the strangulation or of its surgical treatment. He states that in his own list of cases the percentage of deaths from the hernia is not higher than 13.6. The prognosis of herniotomy for strangulated inguinal hernia, therefore, is less unfavorable in infants than in grown-up subjects, as in the latter the mortality under antiseptic conditions is about nineteen per cent. In the total number (14) of cases of umbilical hernia the mortality was fifty per cent., and in those cases (11) which were treated antiseptically, 36.3 per cent. In considering the difficulties of diagnosis in cases of strangulated hernia in young infants, the author remarks that in many of his collected cases the occurrence of urinary retention was noted. He holds that in doubtful cases the hernial rings should be explored, and that when the symptoms of strangulation are clear, herniotomy should not be delayed after a warm bath and taxis with the patient under an anæsthetic have proved useless.—*British Medical Journal.*

The Influence of the Liver in the Development of Pancreatic Diabetes.—Although we have learned that certain lesions of the central nervous system and destructive changes in the pancreas respectively are attended with glycosuria, the etiology and pathology of diabetes mellitus are yet unexplained. Whatever the chemic and metabolic changes upon which the excretion of sugar in the urine depends, there is evidence that no small part in the morbid process is played by the liver, of whose multiplicity of function we really know comparatively little. There is good reason for believing that under normal conditions the liver either stores up or converts into other bodies a substance allied to sugar, and which, under certain morbid conditions, appears in the urine as glucose. Additional evidence of the influence of the liver in the development of diabetes is furnished by the results of some experiments detailed at a recent meeting of the Berlin Physiological Society by Marcuse, who undertook to determine if the dia-

betes that appears after extirpation of the pancreas manifests itself in case the liver is also removed. As the animals experimented with were likely to die sooner in consequence of the two operations than after extirpation of the pancreas alone, the question arose as to whether or not the animals would live long enough to afford time for the development of the diabetes. To decide this point a series of observations were made upon nineteen frogs. It was found that in the twelve of these in which diabetes developed, this appeared within the first day or two, the animal living on an average for five days. The proportion of sugar contained in the urine, as determined by polarization, equalled 9.4 per cent. In a second series of almost parallel cases, both liver and pancreas were removed, with the result that in not one of the animals did the diabetes develop. These animals lived for from one to five days after the operation. The amount of urine excreted was considerable, though not so great as in the case of the animals from which the pancreas only had been removed. In explanation of the influence of the liver in the development of the diabetes that follows removal of the pancreas, it is suggested that there is formed in the liver a substance that, while not itself sugar, is yet of importance in the development of diabetes (perhaps a sugar-forming ferment), or that certain elements in the blood that are acted upon by the liver remain in the circulation after extirpation of this organ, and bring about decomposition of the sugar present after extirpation of the pancreas.—*Medical News.*

The Treatment of Cystitis in Women.—According to Dr. Lutaud, the treatment of cystitis in women presents important characteristics, not only because the etiology of the affection is distinct, but because it often occurs with remarkable suddenness and acuteness. This inflammation is often the consequence of confinement or of the traumatism of an operation. Sometimes a very insignificant matter will cause it, such as the application of a tampon of gauze or wadding to the neck of the uterus, which induces a very painful vesical tenesmus. There are two distinct varieties, the acute and the chronic. In the former, the first indication consists in quieting the tenesmus and the pain. The medication is above all local; sedatives are used, opium and belladonna being especially indicated. The following suppositories are prescribed: Morphine hydrochloride, cocaine hydrochloride, each, three-twentieths of a grain; extract of belladonna, three-fortieths of a grain; cacao butter, forty-five grains. One of these should be used every four hours until the tenesmus and the pain have disappeared. Belladonna may be replaced by hyoscyamus if morphine or opiates are not well borne, and the following formula substituted: Cocaine hydrochloride, three-twentieths of a grain; extract of hyoscyamus, three-tenths of a grain; cacao butter, forty-five grains. Three or four of these suppositories may be employed during twenty-four hours. Rectal injections of laudanum are very useful. If there is insomnia, chloral may be given, always in enemata, and the minimum dose should be sixty grains for an adult. This formula is advised: Chloral hydrate, sixty grains; yolk of an egg; water or milk, two ounces and a half. Hypodermic injections of three-twentieths of a grain of morphine are still better for quieting the paroxysms of pain. Poultices, hip baths, and fomentations on the hypogastrium, are useful adjuvants to the local treatment, which is to be preferred to general treatment during the acute pains. Topical applications and anodynes may also be applied in the vagina. When it is a question of combating inflammation of the neck of the bladder, belladonna or cocaine may be employed as follows: Camphorated lanolin, four hundred and fifty grains; extract of belladonna, thirty grains. This is spread on a tampon of wadding and introduced night and morning into the vagina. When the pain is very sharp, a small tampon of wadding saturated with a solution of fifteen grains of cocaine hydrochloride in three hundred grains of distilled water may be employed. Treatment by the stomach should be cautiously employed during this period. Aside from hypnotics, there are very few remedies to suggest. No benefit is obtained from balsams. Oxalic acid has given the author only doubtful results in women, especially during the acute period, although he has seen painful symptoms ameliorated by the prolonged use of the following mixture: Oxalic acid, eight grains; syrup of bitter orange peel, four hundred and fifty grains; distilled water, three ounces. A dessertspoonful of this is to be taken every four hours. During the chronic period local and general medication must be employed at the same time. When inflammatory and painful symptoms are diminished, intra-vesical medication may be applied and afterward irrigation. A rubber or a glass probe, perfectly aseptic, is introduced, and to the end of it a syringe, holding from three to four ounces, is attached. Antiseptic solutions are used in preference, such as: Boric acid, six hundred grains; sodium borate, seventy-five grains; distilled water, a pint and a half. A rapid jet should be pushed through the syringe, which is then drawn away to allow the liquid to escape. Not more than an ounce and a half should be injected at a time, and it is still better, when the bladder is irritated, not to inject more than an ounce. Dr. Lutaud does not advise injections of nitrate of silver; he prefers iodoform, the action of which is more efficacious, especially in cystitis of blennorrhagic origin. He employs the following method: Washing with a solution of boric acid first, then an injection of four ounces of tepid water to which has been added a teaspoonful of the following emulsion: Powdered iodoform, four hundred and fifty grains; glycerine, six hundred grains; distilled water, three hundred grains; tragacanth, four grains. Blue pyoctanin has been suggested by Neucki, of Warsaw, in injections, for blennorrhagic cystitis. As with all vesical injections in women, it should not be used except in chronic cystitis. Dr. Lutaud has obtained good results with the following solution: Blue pyoctanin, fifteen grains; boiled distilled water, a pint and a half. This is to be injected night and morning, and its use should be continued, if it is well borne, during a period of from ten to fifteen days. General medication is useful in chronic cystitis. Dr. Lutaud has had occasion to try pichi (*Fabiana imbricata*) in cystitis following gonorrhœa in women, and obtained good results. The following mixture was prescribed: Extract of pichi, one hundred and fifty grains; tincture of Cannabis indica, thirty grains; linden water, three ounces and three-quarters. A desertspoonful of this is to be taken every four hours. Another formula, in which buchu is associated with hyoscyamus and ammonium bromide, is the following: Ammonium bromide, one hundred and fifty grains; tincture of hyoscyamus, seventy-five grains; fluid extract of buchu, one hundred and fifty grains; distilled water, two ounces. A teaspoonful is to be taken every four hours. If there is pus in the urine, the following drink is prescribed: Benzoic acid, fifteen grains; orange-flower water, an ounce and a half; boiled water, twenty-eight ounces; sugar, three ounces. This is to be taken by the glassful between meals.—*Journal de Médicine de Paris.*

Southern Illinois Medical Association.—The twentieth semi-annual meeting of the Southern Illinois Medical Association was held November 15th and 16th, in Duquoin, and was called to order at 10.30 A.M., by President Dr. McKenzie. There were about twenty-five members present out of a total membership of one hundred. The address of welcome was delivered by Dr. L. Dyer and Professor C. W. Harris, responded to by Dr. Mitchell, of Carbondale. Ten papers were read.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, January 26, 1895.

NAVAL STAFF RANK.

THE bill now before Congress to reorganize the personnel of the Navy and Marine Corps of the United States is calculated to do great harm in many directions. The Medical Corps particularly will be placed in an anomalous and degraded condition. Bad as it is already, it will be in a still worse condition if all the absurd and unreasonable provisions become part of the proposed law. It would indeed seem to be the purpose of the framers of the bill to so heap indignities upon the Medical Corps as to make positions therein almost untenable by the defiantly invidious distinctions in favor of the line. Not content with the fact that rank in the Medical Corps is relative only, it is proposed that the grades be lowered and the meagre and corresponding privileges of the same be proportionately curtailed.

The sole officer in the Medical Corps on the active list having the relative rank of commodore, is the Surgeon-General. The bill providing for the abolition of this rank promotes all the present occupants of that grade in the line to the next higher, that of Rear Admiral, while with the staff corps there is an actual drop to the next lower grade—that of Captain. This of itself abolishes all distinction for the ranking officer of the Medical Corps, virtually placing him on a par with the medical directors, with the cool courtesy of retiring in that grade. No argument is made in support of such a measure, not even that of public economy, for indeed the latter could not be, inasmuch as the salary of the Surgeon-General is fixed by law. On the contrary, however, the creation of the ten additional Rear Admirals for the line, contemplated in the bill, will involve an additional expense of $10,000 per annum.

Then again in regard to the time for retirement, with the well-earned privileges pertaining thereto, a marked distinction is made in favor of the line as compared to the staff officers. The line officer receives his education from the Government, the medical man educates himself, enters the service when he is older than his brother of the line, and yet has virtually to serve much longer before the period for retirement arrives. The line officer can count his time before the medical officer is able to do so, and thus the latter becomes the loser in a double sense.

The line officer may thus retire as early as the age of fifty, while the staff officer, who has educated himself, can never do so before fifty-six, and often not until sixty-two, the latter being the time for compulsory retirement.

Another point in the bill deserving of notice is the interference with the proper professional functions of the surgeon by such, even junior line officers, as may be deck officers at the time. While such breaches of consistency are not apt to occur in the ordinary run of affairs, they are rendered quite possible by the proposed new relations of the different corps. The whole trouble in this direction comes of the elastic and meaningless construction of the so-called privileges of relative rank—a something to speak about, but nothing to act upon. No one outside of the Navy of the United States would, for a moment, think of placing authority concerning medical matters in any other than medical hands. Wherever there is responsibility there should necessarily be power and force to sustain it. Nowhere but in the United States Navy is such interference on the part of the line officers possible. Everywhere else the surgeon for the soldier and the sailor is supreme in his own department. Everywhere else the surgeon has the self-respecting position of positive rank, is on an equal footing with the corresponding officer of the line, and can even sit with them at the same table and be considered a gentleman of equal standing.

If this proposed bill becomes a law the outlook for the efficiency of an important corps of the Navy is a very serious one. Far from being attractive now for young medical men desiring to enter the service, it will be made still less so. For years the candidates for examination in the medical corps have been growing fewer and fewer, notwithstanding the widest advertising of existing vacancies. This condition of affairs is by no means due to the fact that service as it should be in the Navy is not considered within the range of the laudable ambition of a well-educated man, but simply that the restrictions to his usefulness, the petty thrusts at his self-respect, the slow advancement, and poor pay are the ruling and potent arguments to the contrary. What is asked is not that any extra expense shall be incurred in giving the naval surgeon his due, but that in rank and pay he be placed on the same footing as his brother in the army. If this is not done and proper appreciation is not shown for the valuable and indispensable work of a learned profession, the arm of the service representing it will not only be irretrievably crippled, but will eventually look in vain for applicants to fill its already sparse ranks.

CAR VENTILATION.

No one who, for his sins, has to travel by rail in winter, will dispute the fact that much is yet lacking in the way of the proper ventilation of passenger coaches. In this respect the drawing-room and sleeping-cars are much worse than the ordinary day-coaches. In the latter, especially on accommodation trains, the doors are constantly being opened and a breath of fresh air must occasionally slip in, but on the vestibuled train there is none of this relief, everything is hermetically sealed, and neither fresh air can enter nor carbonic acid and other pulmonary exhalations escape. Doubtless the remedy for this is difficult, but it is not impossible. Car-builders know what is needed, and they will

find the means to supply it, whatever the additional cost of construction may be, when they find they must.

A committee of the Master Car-builders' Association not long since prepared a report on this subject, a part of which is quoted by Dr. G. P. Conn, in a paper on car sanitation, read at the Montreal meeting of the American Public Health Association. In this report the committee summarizes the ideal condition of car ventilation as follows :

"1. The admission of thirty cubic feet per minute per passenger of fresh air, and the carrying off of an equal amount of foul air, summer or winter.

"2. The fresh air so admitted must not be moving at a speed of more than three or four miles per house in winter-time.

"3. Fresh air admitted must be of a temperature in winter-time of about seventy degrees F.

"4. Fresh air so admitted in winter-time must have added to it a proper degree of moisture for the temperature at which it is admitted, according to the average humidity of the atmosphere, when at seventy degrees in the climate in which the cars are running.

"5. No system of winter ventilation can be more successful, unless means for the fresh-air supply are provided independently of, and separately from, the windows and doors, as well as the ventilators for carrying off the foul air.

"6. The fresh warm air should be distributed through as many openings and as low down as it can be conveniently arranged for, and the foul air should be carried off through as many small openings in the roof of the car as can conveniently be arranged for in winter.

"7. The ventilation should be entirely independent of the speed of the train, and act as well whether the car is standing or running.

"8. The ventilation should be so arranged that there will be a plenum or slight excess of pressure inside the car, so that all drafts will be outward instead of inward, and smoke and dust thus excluded.

"9. It is most desirable that double windows should be used, and so arranged that they can be locked fast in winter-time, but readily opened in summer-time.

"10. It is most desirable that an inside swinging-door be used, so as to form an air-lock or inside vestibule, to prevent the admission of cold air and dust every time the doors to the platforms are opened."

No one will probably find fault with these conclusions, for they are eminently sound, and they prove that car-builders can conceive of an ideal even if they do not strive to attain it. The problem now remains, how can travellers profit by the car-builders' knowledge?

Two Excellent Hints for Practitioners.—Dr. Cocksedge, of Wales, places the following "tips" at the disposal of his brethren : If you have a fatiguingly deaf patient to talk to, place the ear-pieces of your binaural stethoscope in the patient's ears, and talk into the chest-piece, and you have an excellent ear-trumpet. If you leave your spectacles at home, being old and apresbyopic, make a hole with a pin in the corner of your visiting card, and you can read your clinical thermometer or anything else.—*Medical Press.*

LODGE PRACTICE.

A Canadian judge has recently given a decision that should be of interest to lodge doctors (*Canadian Practitioner*). In the case in question, "according to the general by-laws of the lodge, no member was entitled to any 'benefits' if incapacitated for work by venereal disease, or any other contracted in consequence of his own wrongdoing. The regular surgeon of the lodge attended a member for certain sequelæ of syphilis, and sent in his bill in the ordinary way. Payment being refused, he sued his patient, but was nonsuited by the judge on the ground that the contract between the doctor and the lodge did not show that any exception was to be made in such cases." The moral of this is that lodge doctors must be very careful in the wording of their contracts. Unless the exception is specified, he may be called on to do obstetrical and major surgical work, and to give treatment of special and difficult character. The lodge doctor gets perhaps a dollar a year for each member. For this dollar he may, therefore, have to amputate the leg, or sit up all night with a parturient woman. "To the physician," says *The Canadian Practitioner*, "who determines to do lodge practice, we have only to say your responsibilities will depend upon the provisions of your contract. In deciding to give up certain prerogatives of manhood, look into the matter in a business way, and make the best terms you can. The best will always be poor enough."

THE INGESTION OF URIC ACID.

Dr. Alexander Haig resumes the subject of uric acid and its relation to tissue changes in an article on the "Introduction of Uric Acid into the Body" (*British Medical Journal*, December 8, 1894). Dr. Haig finds that if one takes uric acid by the mouth the effect is at first to stimulate and produce a feeling of well-being. This, he says, is due to the fact that the acid thus introduced lessens the excretion of uric acid and clears it from the blood by making that fluid less alkaline and thus less capable of holding the substance in solution. After a time, however, the blood resumes its alkalinity, uric acid is taken up, and the various results such as lassitude, headache, high tension pulse, etc., of uric-acid excess are brought about.

Dr. Haig asserts that in an ordinary diet containing meat, soup, fish, etc., a man takes about three grains of uric acid into his system daily, or about one thousand grains a year, or in twenty years three pounds. The writer adds, that by proper diet the amount of uric acid taken in with the food can be reduced at least one-half. By this much, he thinks, one can reduce the liability to the uric-acid diseases, such as gout and rheumatism, later in life.

In order to cut down the uric acid ingested as food one must leave out of his bill-of-fare soup, beef-extracts, fish, meat, tea, and coffee. The logical inference of Dr. Haig's statements would therefore be vegetarianism. Since many gouty and rheumatic people do extremely well on a meat diet, there must be a fallacy somewhere in the doctor's arguments. Whoever explains this fallacy will explain also the fact that some doctors recommend a nitrogenous diet to gouty and

lithæmic patients, while others advise just the reverse.

It is probable that the secret of it all lies in the fact that a nitrogenous diet is usually a low diet, and that a small amount of digestible food, just enough to sustain nutrition, forms the best diet irrespective of any precise regulation as to its quality. Most people of uric-acid habit eat too much.

PATHOLOGICAL ALTRUISM.

The spirit of humanitarianism, which we are told by Mr. Benjamin Kidd is the dominant and saving character of modern social life, shows itself in fantastic as well as in serious and well-directed efforts. The care of the poor, the preservation of health, the prevention of disease, the establishment of homes, workhouses, hospitals, and asylums are all indications of social progress and a genuinely humane spirit. But along with this there are certain pathological manifestations of humanitarianism which often do much evil and always cause much distress to intelligent minds. Such efforts are shown in anti-vaccination societies, anti-vivisection societies, and intemperate advocates and enforcers of an impossible abstinence from poverty, alcohol, tobacco, Sunday newspapers, corsets, etc.

The victims of pathological altruism are always seeking new evils to attack and organizing new societies to promulgate their doctrines.

It looks as though England would soon be the home of a new society for supervising the treatment of patients in hospitals. Mr. W. T. Stead, who among his perhaps saner vagaries does not approve of Chicago, has recently issued a Christmas number of his *Review* in which he attacks the hospital physician. He introduces among his characters a doctor, and prints this interesting dialogue:

"'But what experiments are you making, doctor?' 'Invaluable experiments,' said he; 'I am cultivating the bacillus of typhoid fever. I have converted this hospital into a physiological laboratory. The other day I inoculated five perfectly healthy subjects. It is true that they were healthy—that is, they were healthy at the time I pricked them—but they were not healthy five minutes afterward; and after all it is only a question of time. They took typhoid fever in due course, and are going through all its stages.' Ethel's eyes were dilated with horror. 'You don't mean to say that you give healthy people typhoid fever merely in order to experiment?' 'Of course;' replied he, 'we all do it. What are the great London hospitals for but to collect the poor in order that they may be used as experiments for the benefit of the rich? Surely you don't need me to tell you that.' And so on. Needless to say that this doctor came ultimately to great wealth. His discovery of the possibility of preserving the microbes of cholera in ice, and the power which that gave him of regulating the population in accordance with the commercial needs of the country, was in itself enough to render his services of great value to the coming plutocracy."

We do not propose to criticise Mr. Stead's medical views of hospital physicians or to attempt a defence of the doctor. Neither criticism nor defence is needed. The untruth and unfairness of the picture drawn are too gross. But Mr. Stead's performance has an interest as an illustration of an unbalanced, ill-informed, and mischievous mind.

MEDICINE IN NEW YORK EIGHTY YEARS AGO.

All physicians of the present generation—or, at any rate, all who have had personal experience in the matter—know how difficult it is for anyone to establish himself in practice in New York City. But probably not all who know this understand that a similar condition of over-competition has existed in this city since the days when it first became the metropolis of the country. Yet such is the fact.

We recently saw a letter, written eighty years ago, in which the conditions to be met by a would-be practitioner in New York are stated in terms that might be applied without alteration (except, of course, as to the actual number of competitors) to the conditions of today. The letter was written by a then prominent lawyer of New York, and addressed to a young physician of his acquaintance who contemplated settling in the city, and who had asked advice as to the feasibility of the project. The writer of the letter, though not himself a physician, was fully informed as to the status of medical affairs in the city, as proved by another letter he had previously written, in which the merits of the different medical schools in New York were fully canvassed, a letter to which we may make more extended reference at another time. What, then, is the advice which he is able to give the aspiring young physician? Let us see.

Writing under date of August 10, 1814, he says:

"I have given your letter close attention, and after all, I find myself somewhat at a loss what to say. New York is preferable to any other place, at least to any place in the country, if a physician can only once get footing. Dr. ——, of whose capacity and popular manners I need say nothing to you, made an experiment, as you know, of a little more than two years, and certainly did not in that time succeed. I very much doubt whether he supported himself during that period, taking it together (but this in confidence). Had he remained seven years longer, I doubt not that he would have found himself in lucrative practice at the end of that time. . . . The only way I have known young physicians rise into early notice and practice is by connecting themselves with some older member of the profession, who soon has retired and left them in possession of his business. I am told there are now in this city upward of five hundred physicians, most of whom find difficulty enough in earning their daily bread."

There is more in the same vein, and the only grain of encouragement the writer feels justified in offering is this: "Notwithstanding [all the discouraging facts noted] I am by no means certain that a young man of genius, learning, and steady habits might not make his way among them [the host of competitors], especially if he happened to pitch his tent on a favorable spot."

That surely is not a very roseate presentation.

"Genius, learning, and steady habits," combined in one individual, ought, one would think, to carry the individual almost anywhere, yet even this cluster of accomplishments was held to give their possessor only a fighting chance in New York. This was apparently a fair estimate of the conditions that marked the physician's struggle for existence in the metropolis in 1814; it is just as fair an estimate for 1894.

News of the Week.

New York Ophthalmological Society.—At the annual meeting of this society the following officers were elected for the ensuing year: *President*, Dr. F. N. Lewis; *Vice-President*, Dr. H. D. Noyes; *Secretary*, Dr. F. D. Skeel; *Committee on Admissions*, Drs. Mathewson, Dennett, and Roosa.

Dr. F. J. Quinlan.—At a recent meeting of the Faculty of the New York Polyclinic, Dr. Francis J. Quinlan was elected Adjunct Professor of Laryngology and Rhinology.

Dr. A. B. Cook, of Louisville, formerly professor of surgery in the Kentucky School of Medicine, died on January 2d, aged sixty-five years.

The Lane Hospital, at San Francisco, Cal., has a unique record. It was built by a surgeon, Dr. L. C. Lane, at a cost of $160,000, and when it opened, on January 2d, Dr. Lane performed the first surgical operation. It has received as endowments, from Captain J. M. McDonald, $58,000; from Claus Spreckels, $25,000, and from Mr. A. B. McCreery, $6,000.

A Good Example.—The city of Sydney, Australia, has imposed a fine of one pound sterling upon any person convicted of spitting upon the floor of public buildings or upon the street.—*Boston Medical and Surgical Journal.*

Dr. R. H. Cummins, of Wheeling, W. Va., died December 13th of diphtheria, contracted while in attendance upon several severe cases of that disease. He was a graduate of the University of Pennsylvania and a man of fine character. He met death fearlessly, a martyr to his chosen calling.

The Medical Department of Vanderbilt University recently distinguished itself by inviting pugilist James Corbett to lecture to its students on physical culture. Even astonished comment pales before the shameful fact.

Dr. Mary Woolsey Noxon, a well-known homœopathic physician of this city, died suddenly of apoplexy recently, while calling on a patient.

Proposed Legislation for the Board of Health.—The New York City Board of Health propose to ask the Legislature to amend the act now in existence with regard to the free distribution of vaccine for the relief of persons suffering from small-pox, the organizing of a corps of physicians to guard against the spread of the disease, and the sale for the city's benefit of whatever vaccine is left on hand, so as to include powers for similar use of antitoxin and treatment of diphtheria. An act covering the desired amendment has been prepared and will be forwarded to Albany by President Wilson.

Association of American Anatomists.—The Seventh Annual Meeting of the Association of American Anatomists was held in the Medical Department of Columbia College, New York City, December 28 and 29, 1894. The President, Professor Thomas Dwight, of Harvard Medical School, presided. Dr. E. C. Spitzka, of New York City, was Chairman of the Executive Committee; Dr. Burt G. Wilder, of Cornell University, Secretary of the Committee on Anatomical Nomenclature; Dr. D. S. Lamb, of the Army Medical Museum, Washington, D. C., Secretary and Treasurer. The Secretary reported the deaths of Dr. A. C. W. Beecher, of Jefferson Medical College, Philadelphia, and of Dr. Middleton Michel, of the Medical College of South Carolina; also the resignations of two members, making a membership of 103, which was increased to 114 by the election of 11 new members.

The following papers were read and discussed: 1. "The Best Arrangement of Topics in a Two Years' Course of Anatomy in a Medical School," by Dr. Gerrish. Discussed by Drs. Huntington, Frank Baker, Wilder, Bevan, Allen, Shepherd, and Lamb. 2. "History of the Development of Dentine," by Dr. Carl Heitzmann, of New York City. 3. "On the Value of the Nasal and Orbital Indices in Anthropology," by Dr. Allen. Discussed by Drs. Wilder, Huntington, and Dwight. 4. "Some Characterizations of Vertebrate Groups in Standard Works," by Dr. Wilder. Discussed by Drs. Baker, Dwight, and Allen. 5. "The Comparative Anatomy of the Cerebral Circulation, with the Exhibition of a Series of Anomalies of the Circle of Willis," by Dr. Joseph Leidy, of the University of Pennsylvania. This paper was read by title in the absence of the author. 6. "Convolutions of the Hemispheres of Elephas Indicas," by Dr. Huntington. Discussed by Drs. Wilder and Baker. 7. "Classification of the Tissues of the Animal Body," by Dr. Baker. Discussed by Drs. Heitzmann, Wilder, Dwight, and Lamb. 8. "Significance of Anomalies," by Dr. Dwight. 9. "Some Muscular Variations of the Shoulder Girdle and Upper Extremity, with Especial Reference to Reversions in this Region," by Dr. Huntington. 10. "Some Anomalies of the Brain," by Dr. Wilder. 11. "The Correlation between Specific Diversity and Individual Variability, as Illustrated by the Eye Muscle Nerves of the Amphibia," by Professor C. J. Herrick. The last four papers were discussed by Drs. Baker, Shepherd, Wilder, and Lamb; Drs. Shepherd and Lamb illustrated their remarks by specimens of anomalies. Dr. Wilder exhibited a frog from which the cerebrum had been removed, and made remarks thereon.

Oysters and Typhoid Fever.—At a meeting of the State Fish and Game Commission held in Albany, January 4th, the State Oyster Inspector presented a report in which he stated that he had fully investigated the subject of the possibility of oysters becoming contaminated with typhoid fever germs while undergoing the "floating process," and that he had found but one stream, situated on Staten Island, where such danger existed. He was ordered by the Commissioners to demand a discontinuance of the use of this stream.

A Skin Disease Peculiar to Foot-ball Players.—The Council of the Medical Officers of Schools Association of England are desirous of obtaining information as to the etiology, nature, and treatment of the skin affection which is reported to be at the present time prevalent among foot-ball players. It is believed to be contagious, and occurs principally on the face, ears, and neck, sometimes on the hairy scalp. It goes through the following stages: erythema, papule, vesicle, and purulent crusts, the latter, on the head, having the appearance of impetigo contagiosa (porrigo).

The Cleveland Medical Library Association.— On November 27th about thirty of Cleveland's representative physicians met and effected the organization of the "Cleveland Medical Library Association." The following officers were elected: *President*, Dr. J. E. Cook; *Secretary*, Dr. P. Max Foshay; *Treasurer*, Dr. O. F. Gordon; *Librarian*, Dr. C. A. Hamann. *Trustees:* Drs. D. P. Allen, H. K. Cushing, H. J. Lee, I. N. Himes, W. W. Holliday, H. E. Handerson, W. A. Knowlton, M. Rosenwasser, O. B. Campbell.

The Eastern Shore Medical Society, Virginia, met at Eastville, Va., December 7th. Dr. E. W. Robertson, of Onancock, Va., presided. The meeting was one of interest and the attendance was large.

The Philadelphia Hospital Trouble.—We learn that Dr. Hobart A. Hare has declined to accept the position of attending physician to the Philadelphia Hospital, made vacant by the enforced resignation of Dr. Judson Daland. Good for Dr. Hare! The Philadelphia physicians show a loyalty to each other which deserves imitation elsewhere.

Dr. Edward J. Kurtzman, of this city, suddenly fell dead on the night of December 30th while returning from a night call.

Treatment of Goitre by Thyroid Feeding.—Professor Bruns has just published the result of his treatment of twelve persons affected with goitre by ingestion of the thyroid gland of sheep or calves. Of the total number, only three remained refractory to the treatment, the remaining nine being either cured or considerably relieved. The dose was from one to two drachms, enclosed in a wafer or a sandwich, and repeated about once a week. By this means Professor Bruns cured four children completely, between the ages of four and twelve. At the end of a fortnight a marked decrease in the size of the tumor was observed, and a month subsequently it had entirely disappeared. In the fifth case, that of a boy, aged fourteen, the goître was accompanied by a cyst. The goître was removed, but the cyst was unaffected by the treatment. In four other cases the result was equally satisfactory. Professor Bruns advises not to exceed two drachms of the thyroid gland, given once a week to the adult, and five drachms to children. In these latter, in any case, the treatment succeeds the best; whereas in aged persons the goitre is but exceptionally amenable, for reasons easily apparent.

Dr. St. John W. Mintzer, who rendered good professional service during the Civil War, and who for a time resided and practised medicine in Philadelphia, died, on December 26th, at his home, China Hall, Bucks County, after a protracted illness, aged sixty-two.

Obituary.

PROFESSOR ALFRED L. LOOMIS, M.D., LL.D., NEW YORK.

The death of Professor Alfred L. Loomis occurred, after a very brief illness, on the morning of January 23d. He was attacked on the Sunday previous with symptoms of pneumonia, which, after the first day, steadily grew more and more grave. To his many friends here and elsewhere the news came with startling suddenness, and it is difficult to realize the extent of his loss in many of the medical circles in which he was such a leading and active figure.

Dr. Loomis was born in Bennington, Vt., October 16, 1831. His early education was obtained at Hoosic Falls and Rochester, N. Y. He graduated from Union College in 1850 and took the A.M. degree there six years later. He graduated from the College of Physicians and Surgeons in 1852. For two years he had an interneship in the hospitals of Ward's and Blackwell's Islands, and then began a general practice in New York. In 1859 he was made visiting physician at Bellevue, and in 1862 lecturer on physical diagnosis at the College of Physicians and Surgeons. Among his publications are: "Lecture Introductory to the Course of 1871–72 in the Medical Department of the University of the City of New York;" "Lessons in Physical Diagnosis," 1872, ten editions up to 1893; "Diseases of the Respiratory Organs, Heart, and Kidneys," 1875; "Peritonitis," 1875; "Lectures on Fevers," 1877; "Diseases of Old Age," 1882; "A Text-book of Practical Medicine," 1884; also, "Climatic Treatment of Pulmonous Phthisis," "Physical Exploration of the Abdomen;" "Physical Signs of Diseased Conditions of the Liver and Spleen," and "On the Use of Opium in Acute Uræmia and Convulsions."

The University of New York conferred on him the degree of LL.D. He married in 1858 Sarah Patterson, of Hoosic Falls, N. Y., and by her had two children. In 1887 he married Mrs. John D. Prince. She and his two children survive him. The children are H. P. Loomis and Mrs. John D. Prince, whose husband is a son of her stepmother. Dr. Loomis was for over thirty years visiting physician to Bellevue Hospital and consulting physician to numerous other public institutions, and was a member of all the leading medical societies. His most energetic activities were devoted to the medical department of the University of New York. When that was burned out, Dr. Loomis was instrumental in furthering the movement to Twenty-sixth Street. Through him "an unknown friend of the University" gave, in 1886, $100,000 to build and equip the Loomis Laboratory, which is a worthy monument to his name and affords every opportunity for the study of scientific bacteriology. This friend, it has been supposed, was Mrs. John D. Prince, widow of the Wall Street broker. Mrs. Prince, in 1887, became the second wife of Dr. Loomis. Dr. Loomis was professor of pathology and the practice of medicine in the University of New York since 1868. For two years before that he was adjunct professor of the theory and practice of medicine. He was an admirable business man, and in his practice he acquired an income generally conceded to be one of the greatest ever secured by a physician in this city. He took an active interest in the Academy of Medicine, of which he was President for two terms up to two years ago. It was largely through his efforts that it became possible to put up the present building.

The Bureau of Charities and Correction has decided that a tablet be placed in the Medical Board room of Bellevue Hospital as a token of respect to Dr. Loomis's memory, also that the flags of the Bureau be placed at half-mast until after the day of the funeral, and that the entrance to Bellevue Hospital be draped in mourning for thirty days.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, January 17, 1895.

D. B. St. John Roosa, M.D., President, Afterward Joseph D. Bryant, M.D., in the Chair.

Nominations for Vice-President.—A vacancy having been left in the office of vice-president by the election of Dr. Bryant to the presidency, Drs. Daniel Lewis, Ellsworth Eliot, and Virgil P. Gibney were nominated. Dr. Eliot declined.

Valedictory Address by the Retiring President was delivered by Dr. Roosa (see page 107).

Inaugural Address by the President-Elect.—Dr. Joseph D. Bryant opened his address essentially in the following words: The foremost duty of one who is honored by his fellowmen is to express his grateful appreciation for the manifestation of confidence and esteem, and to pledge his earnest thought and conscientious labor to the support of the best interests of the charge entrusted by them to his guidance and care. The fact that you have deemed it wise to honor me, and, too, out of proportion to my merit and expectation, by placing me at the helm of affairs in the Academy of Medicine, is a tribute of regard which, while it emphasizes the value of past conscientious effort, none the less admonishes one of the necessity of continuous and untiring endeavor. Indeed I thank you sincerely for this earnest of your confidence, and beg to express the hope that no official action of mine will cause the lodgment of a well-founded regret in the mind of anyone.

Referring then in a general way to the motives which should control us in the conduct of the Academy's affairs, the president reminded the members of the fact, to begin with, that decided differences of opinion were inevitable products of earnest discussion when engaged in by sincere and active minds, whether the subjects under discussion related to politics or to unsettled scientific questions. But the results of deliberate conclusions, when secured by fair means, demanded the sincere support of all who appreciated the importance of wise control, good order, and well-founded prosperity. The endurance and thrift of every organization depended on the honesty, the harmony, and the productiveness of the administration of its affairs. Unfortunate indeed when, for any reason, the canker of discontent or of indifference fastened itself on any organization. Then its material assets—the landed, the structural, and the monetary—were likely to fall with its usefulness.

There were two assets of the Academy to which he wished to call especial attention because each should be cultivated with care and treated with circumspection and forethought. He referred to the books in the library and to the members. The library should be regarded as a legacy from the present to the future of the Academy, and from the present to the future of medical achievement, and indomitable activity should be exercised to secure a sum of money, the income of which should be sufficient to maintain the library on the footing required to keep pace with medical advancement. The larger and more comprehensive the library became, the greater and more enduring would be the fame of the Academy and the measure of its beneficent influence. The other interests of the Academy should also be remembered, its financial exactions should be met with promptitude, and advice on public questions be willingly though discreetly given.

The fact should not be disregarded that there were some members who found it difficult to meet their annual obligations to the Academy. For these the president-elect expressed sincere sympathy, and bespoke for them the indulgence and the aid of the more fortunate members of the organization.

A prompt and large attendance would beget a deeper, a more active and lasting interest, and a more intelligent appreciation of the Academy's work. Finally, he asked that we bear with one another patiently at all times, being assured that all differences would be honest differences, and all conclusions sincere. Should he be able at the end of his term of office, following such distinguished immediate predecessors as Drs. Jacobi, Loomis, and Roosa, to point to increased facilities, increased membership, and increased good-fellowship, then indeed would he be gratified and feel that he had not labored in vain.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting December 17, 1894.

Samuel B. W. McLeod, M.D., President, in the Chair.

How to Examine Sick Children.—Dr. J. Lewis Smith read a paper with this title, although the title was not adhered to strictly. The frequency and fatality of diseases of childhood, and the fact that some of them did not occur at an advanced age or presented different characteristics, made them of special interest. He had heard skilful physicians, who were much sought for in practice among adults, say they did not like to treat sick children. To be a successful pediatrist required much patience and knowledge of childish ways. If the patient were under five years, the physician on entering the room should take a seat a little distant, and without appearing to notice it, first obtain the history from the mother or nurse, and it would be found that usually the suspicious glances of the child at the stranger would cease when it believed itself not to be noticed, and it would begin to act in a natural way and manifest more clearly the symptoms of the disease. While still at a distance, the physician could observe the prominent symptoms of the disease, and thus with the aid of the history obtained from the mother he could often make the diagnosis, and find it confirmed by a closer examination made later. The previous history, the mode of commencement and progress of the present illness, should be obtained. Aural troubles were among those which often could be best located from a distance, when it would be observed that the infant rolled its head, and from time to time put its finger to the ear. The pediatrist must not value his time too highly. Finally, quietly approach the child for a closer examination. Avoid causing alarm. The percussion-hammer, lead-pencil, or watch could be held out as a plaything. One of the most distinguished pediatrists of this country always approached his patients with a watch in hand, the chime of which he would first set in motion.

The Normal Temperature of the Child.—Dr. Smith had had some observations made with regard to the normal temperature of the child, which he believed had not been shown by statistics in text-books. Under six months the rectal temperature had been found, among a large number of healthy infants at the Infant Asylum, to average 98° F.; the axillary temperature, 98.3° F. Between six and twelve months of age, rectal temperature, 98.6° F.; axillary, 98.3° F. Twelve to eighteen months, rectal, 98.4° F.; axillary, 98.3° F. From eighteen to thirty months, rectal, 98.0° F.; axilla, 98.1° F. Dr. Smith thought these observations were important as furnishing a basis for judging of departures from the temperature of health.

Mental excitement was capable of causing a rise of temperature, a marked example having occurred in a child observed by him, in whom any cause for excitement resulted in a rise of five or six degrees above the

normal. Sudden and unaccountable elevations of the temperature continuing for some hours were often due to indigestion or constipation. He had frequently seen the temperature go down next day after moving the bowels.

The Normal Pulse.—In the same cases at the Infant Asylum the pulse was noted during health, and was found to average, under the age of six months, 125 ; from the sixth to the twelfth month, 124 ; twelfth to eighteenth, 115.5 ; from the eighteenth to the thirtieth, 111.8.

Respirations during Infancy.—The average number of respirations under six months had been found to be 44.8 ; six to twelfth month, 34.8 ; twelfth to eighteenth, 35.4 ; eighteenth to thirtieth, 29.8.

Average Time of Dentition.—With the aid of Dr. Purdy, he had kept records of the average time of appearance of the teeth in children at the out-door department of Bellevue Hospital, excluding cases of rickets, which were most common in Italians and next in negroes. In 200 infants without signs of rickets, the first tooth had appeared as follows : In 3 infants at two months, in 20 at five months; in 24 at six months, in 37 at seven months, in 28 at eight months, in 20 at nine months, in 14 at ten months, in 15 at eleven months, in 8 at twelve months, and in 1 at thirteenth months of age. Yet Sir William Jenner had said that if a baby did not get its first teeth by the ninth month it indicated rickets.

Against Cutting Gums.—The belief still prevailed to a wide extent that the cutting of teeth was not only a common cause of painful gums and poor appetite, but also of entero-colitis and other serious maladies which were often allowed to run along until beyond the skill of the physician. He thought our ancestors in the profession were to blame for the wide-spread impression that much disease was due to dentition, since at one time it was a common custom to incise the gums.

When practical, take the temperature in the rectum ; if not, then in the axilla or inguinal region. Examine the head, chest, etc., in turn, as might be required. If the infant had been long sick there would probably be some depression of the occipital bone, especially before the ninth month of age. Dr. Sims had once believed that depression of the occipital bone was the cause of tetanus, but this view had been shown to be erroneous. The depression was due to diminution in the size of the brain from emaciation.

Look for indications of rickets. Cranial tabes occasionally gave rise to laryngismus stridulus. Examination of the fauces should always be made, and might enable one to diagnosticate scarlet fever, as well as diphtheria, etc. Examine the chest if there were the least acceleration of breathing. He used the new kind of stethoscope and percussion-hammer, to avoid approaching near the chest. If there were acceleration and no respiratory moan, it was probably bronchitis, not pneumonia or pleurisy, and the child would complain of the middle of the chest. Expiratory moan usually meant pneumonia or pleurisy, but was sometimes caused by indigestion and flatulence, in which event it would disappear with free movement of the bowels. In case of mitral regurgitant murmur, precystolic murmur, or the two combined, inquire for history of rheumatism. This disease was often denied by the parents, who, however, might recall complaint of "growing pains." The speaker did not believe there was such a thing as growing pain. Rheumatism was more apt to affect the heart in children than in adults. They often continue to go around, and the parents were unaware of the existence of the rheumatism.

Examination of the urine was often neglected, and he had in many cases found albumin and other signs of nephritis to account for obscure illness existing perhaps six months after a mild attack of diphtheria or scarlet fever.

Dr. George T. Harrison opened the discussion. He believed the examination of children required observation, discrimination, and the use of the senses to a degree demanded in hardly any other field of activity. Knowledge alone did not determine the capability of the pediatrist, but, as stated by the author, he must have insight into and adaptability to the individuality and childish character of his little patients, in order to first awaken confidence, love, and obedience. More reliance could be placed upon statements of facts by the mother and nurse than upon their conclusions. Popular impressions as to the influence of dentition and the change of life, constituted the *bête noire* of the profession. It was not always a simple matter to differentiate between bronchitis and pneumonia, and absence of expiratory moan was not sufficient to exclude the latter. Physical signs might also fail or be overlooked. Fever and then a sudden rise of temperature, might mean pneumonia.

Dr. J. Blake White warned against being misled by the conclusions of the mother when asked for the history. Grouping the symptoms in appropriate sequence up to the time of the examination, would aid in locating the lesion and in arriving at a correct conclusion as to the existing ailment. The next step was to gain the confidence of the little patient. Nothing required more tact. He differed from Dr. Smith as to the use of the stethoscope, feeling that the fewer instruments shown the less likelihood of frightening the child. His habit was to examine the back while the child lay on the mother's shoulder. Very often the sounds anteriorly would be transmitted to the ear placed posteriorly. In examining the throat, have the little one wrapped in a sheet, restraining arms and feet. The head might be held between the physician's knees, the body extended on the mother's lap.

Lancing Gums.—Dr. White believed in lancing the gums when they were swollen and inflamed, and were evidently the seat of irritation and pain. One should cut squarely down to the tooth. He had never seen any harm come from proper lancing, but had seen irritation follow improper lancing or failure to cut to the tooth.

The speaker had seen an erythema due to excitement, perhaps to the physician's presence, which had no relation to the disease. He advised taking the temperature by the rectum.

Dr. Illoway said the first thing he did, in order to save time, was to place the thermometer in the axilla, the mother holding the child's arm over its body. All one had to do to judge of the rectal temperature was to add one degree. He then got the history from the mother, holding her down to facts, and not placing too much reliance upon her statements as to these. Diseases of the brain gave signs on the forehead ; of the respiratory tract, on the face down to the lower lip ; of the abdomen, on the mouth and chin. Careful observation of the features would indicate which of the three regions was implicated. He then had the child stripped and examined the whole body, giving special attention to the seat of the major disease. He had long ceased to look for rheumatism in cardiac disease, believing the latter existed without the former. Broncho-pneumonia and capillary bronchitis presented two entirely different pictures.

Dr. Smith, in some concluding remarks, said he would not be willing to say there was an endocarditis in children independent of scarlatinous affection or rheumatism. As to lancing the gums, he thought one could get along as well without it. If the gums were red and irritated, there must be some other condition to account for the irritation. He did not think the physiological process of normal dentition was to be interfered with any more than any other physiological process.

A Treatment of Diphtheria upon Antiseptic Principles.—Dr. Charles G. Amende read a brief paper, supplementary to a former one, in which he gave fur-

ther experience with treatment of diphtheria by quinine internally, and local painting with boroglyceride, alum, and creosote solution. The applications could be made every two hours or oftener, and gradually diminished in frequency as the membrane disappeared. But chief credit was given the action of quinine, administered in rather large doses and continued until the temperature fell to 99° F. Out of over one hundred cases treated the past four years by this method, only four had died, and in these special circumstances were connected with the history.

Dr. Proben spoke against the method of treatment, saying that boracic acid was only mildly antiseptic and liable to early change; that the application could not reach the nose nor the larynx, and was less harmful than irrigation of the nose. The child's stomach ought not to have put into it any nauseous drug, especially quinine.

Nomination of Officers.—*President*, Dr. McLeod (renominated), Dr. George T. Harrison; *Vice-President*, Dr. A. D. Ruggles; *Recording Secretary*, Dr. P. B. Porter; *Corresponding and Statistical Secretary*, Dr. N. G. Bozeman (Dr. Van Arsdale declining a renomination); *Treasurer*, Dr. John Hinton; one *Member of Executive Committee*, to serve four years, Dr. T. H. Burchard and Dr. John A. Wyeth.

Correspondence.

MEDICAL AFFAIRS IN CANADA.

(From our Canadian Correspondent)

MEDICAL COUNCIL ELECTIONS—THE FIVE YEARS COURSE IN MEDICINE—THE FAKIRS AND THE PATRONS—THE QUESTION OF LODGE PRACTICE—PROVISION FOR TREATMENT OF THE INSANE IN CANADA—POST-GRADUATE INSTITUTION—ANTITOXIC TREATMENT OF DIPHTHERIA.

The members of the medical profession in the Province of Ontario have taken considerable interest in the recent election of members of the Ontario Medical Council, and it is generally felt that there is reason for congratulation on the choice made. By the new enactment of the Legislature a redistribution of the constituencies was provided for, so that there are now seventeen territorial representatives instead of twelve, as formerly. In addition to these there are nine collegiate representatives, each institution in the Province with degree-conferring powers having the right to appoint a member, and five homœopathic representatives. The old Council had, by some of its regulations and investments, met with sufficient criticism to cause the formation of a medical defence association, the existence of which added considerably to the interest taken in the recent contests. In several of the constituencies the medical defence association had candidates, and several of these have been successful. The leader and head of the association was elected in one division by a large majority, and in another the president of the Council met with defeat. The feeling is, however, that although some good men have been defeated the presence of new and vigorous blood in the Medical Council will in the end be only productive of good to the whole profession. The desire of the profession throughout the Province is to make the Council as representative a body as possible, and for that reason the next agitation will be to take from all institutions, except those which confer degrees in medicine, the right to send representatives to the Council. As the law is at present two institutions, one of which has merely a nominal existence, and the other has abrogated its degree-conferring powers, appoint representatives. With this proposed reform the Medical Council will probably remain unchanged for the next four years.

The new regulation of the Medical Council, that all students of medicine before coming up for the final examination before the board of examiners of that body (without a license no one can legally practise medicine in the Province of Ontario), must spend five years in professional study, is likely to give the utmost satisfaction. The colleges of medicine have already made the necessary alteration in their curricula, and the students who have entered the fall term this year have done so with the clearly understood regulation in view that a five years' course is now imperative. In spite of this, however, the number of new students in the different colleges remains about the same as in other years. Several American institutions have literally flooded the Canadian post-offices with announcements during the past summer, and it is not to be wondered at that quite a number of Canadian students now attend American colleges, where they are assured they can attain to, in two or three years, what will take them five years to reach in Canada. Such students seldom return to practise here, as the regulations of the Medical Council are so strict that it is felt that only those who have complied from year to year with the requirements laid down by that body, can be at all hopeful of succeeding at the examinations. Truly the medical profession in Canada is well protected, for each province of the Dominion has a strict code of medical laws. Fortunately the public feel that they also are protected in this way against the invasion of the fakir and charlatan.

One of the regulations of the Medical Act in Ontario, is that anyone who has been registered and is clearly proven to be guilty of disgraceful and infamous conduct, may be brought before the discipline committee, and if after a fair trial he is found guilty his name may be struck off the register, and his right forfeited to practise in the province under severe penalty. Several have been brought to book rather severely before this committee, and although there is a right to appeal to a court of justice, in every instance the decisions of the committee have been ratified. A few of these malcontents, newspaper advertisers, who most dishonestly promise miraculous cures in hopeless cases, and whose swindling of the public has made the Medical Council's strict regulations more popular than ever, have been recently attempting to get the sympathy and support of a political organization, known as the patrons of industries, and through the influence of that respectable body, have vainly hoped to effect legislation, during the next session of the parliament, which would take from the Medical Council the power it now holds of striking the names of quacks and fakirs from the Ontario register. The patrons in the Legislature are believed, however, to be too intelligent a class of men to advocate such a scheme, and this latest effort of the much discredited medical charlatan is doomed to failure. Ontario gives no quarter to quackery.

The question of lodge practice in Canada has during the past year been exciting considerable attention. At the annual meeting of the Ontario Medical Association a strongly worded resolution was passed declaring against all lodge and contract practice, and as this association has a membership of over seven hundred medical men from every portion of the Province the influence of its action is wide-felt. It is a fact that in a portion of Canada, the people have given a strong patronage to beneficiary societies. In a small town of two thousand inhabitants there is often five or six of these societies, so that frequently a greater number of the male population belong to one or other of these different orders. Each society has its own physician, although there is nothing to prevent a "pushing" medical man, by one means or another, fair or unfair, from securing the contract of furnishing medical attendance for the members at so much a head. The price paid averages about a dollar a member, including medicines. In one city in Ontario it is said some medical men have contracts for attending as many as two thousand mem-

bers of different societies. The feeling is that all contract work is degrading to the profession, and if the effort now being made to discourage medical men from having anything to do with lodge practice is successful, a great and growing evil will be checked.

The care of the insane in Canada has for many years been a serious problem, and it is only a few years since the distinguished English alienist, Dr. Tuke, made such an unfavorable report on the condition of some of the Canadian asylums. Fortunately his severe criticism was confined to the Province of Quebec, and since then great improvements have been made in the asylums of that province. Ontario has sustained its reputation as the banner province of the Dominion, by excellent provision for the insane of its population. There are at present over four thousand insane persons in the care of the five well-equipped asylums maintained under the care of, and managed by, the government of the Province of Ontario. The management of these institutions has been such as to secure the fullest confidence of the profession, and the results of treatment have been equal to any in the world. Ontario has just reason to be proud of its asylums, although they are maintained at a very much reduced figure when compared with similar American institutions. True, some wily politicians have endeavored to criticise the kitchen expenditure in one or two instances, but this only serves to prove how carefully and judiciously these institutions are conducted. As an example of how economically everything is managed, it may be mentioned that the lowest salary paid to the medical superintendent of any asylum for the insane in the State of New York is four thousand dollars per annum, including a fine residence and living for himself and family; while in Ontario the highest salary paid to a medical superintendent in a similar position, and with fully as much responsibility, is two thousand dollars per annum. The opening of a new asylum at Brockville adds considerably to the provision made for the treatment of the insane in Ontario, and the excellence of the equipment of this new institution is calculated to increase the confidence felt by the medical profession throughout the Province, that in committing their patients to these institutions they are placing them where they will be well and carefully provided for. The tendency in Ontario is to make these institutions more like first-class hospitals, full of cheerful comfort, and thus do away with the old idea that an asylum resembles and is managed like a prison.

There is every probability that in the course of a short time a post-graduate course will be established in the city of Montreal for the benefit of the large number of Canadian medical men who have expressed themselves desirous of having such an institution in the Dominion. Montreal or Toronto, with the hospital advantages and wealth of clinical material possessed by each, would furnish a very desirable centre for such an institution, but in establishing such it will be necessary to decide which is likely to prove the most advantageous in every respect. Surely in deciding the clinical facilities these cities offer and which are so requisite for the complete success of a post-graduate school, the jealousies which sometimes come to the front when the claims of these two great commercial centres are being compared, will not be seen. Either Montreal or Toronto will do, but the feeling is that Canada must have only one centre for post-graduate work.

The antitoxic treatment of diphtheria has during the past few weeks received considerable attention in Canada, and the reports are most favorable. One careful observer, who used it only after the Klebs-Loeffler bacillus was found in each case, had a percentage of 74.2 recoveries.

Insanitary Dwellings in Birmingham.—It is said that there are 10,000 houses unfit for habitation in Birmingham, England, which are nevertheless crowded with wretched human beings.

"IS IT THE BEGINNING OF THE END?"

To the Editor of the Medical Record.

Sir: It is with a certain degree of reluctance and hesitancy that I venture to criticise Dr. Weir's fascinating paper under the above title in a recent number of the Medical Record. It is a most scholarly production, founded evidently upon honest convictions, and revealing on the part of its author a liberality that invites candid criticism. The writer has studied closely and taught us much about crime and the psychology of crime; and yet it seems to me that his conclusions are somewhat too pessimistic. Besides taking too limited a view of the present age, which of itself is apt to warp one's judgment, he draws comparisons between our nation and certain extinct nations of the past that do not seem to me to be entirely warranted. So gloomy are the closing paragraphs of his essay that I would willingly believe he has been prejudiced by the field of study in which he has done such splendid work. To think of our country, with all its youthful activity, its vast extent, its unlimited resources, its power, commerce, and industrial capacity, its science, literature, and art, as soon to follow in the wake of Rome, Egypt, and Assyria, is not only sad but appalling. If we are already at the beginning of the end, why proceed? If the "social cataclysm" is already in view, what purpose can there be in our struggling to postpone merely for a brief time the inevitable?

History and statistics have always taught different lessons to different men. For my part, I see differences between our modern civilization and the ancient civilizations referred to by Dr. Weir, that tend for good and far outweigh the resemblances that tend for evil. In the first place, the Assyrians, the Egyptians, and the Romans were all unchristianized. They had their respective religions, but they were stoical, coldly philosophical, and fatalistic. Looked at from every point of view, Christianity (using the term in its broadest, historical sense) must be admitted to have introduced among the nations a standard of morality and a principle of living that were quite unknown to them before. All historians, sacred and secular alike, admit the irresistible influence of the Christian doctrines toward raising the moral tone of the nations by whom they were accepted. So antagonistic an authority as Gibbon is forced to confess the power and influence of Christianity in modern civilization, when he states that, "after a revolution of thirteen or fourteen centuries, that religion is still professed by the nations of Europe, the most distinguished portion of human kind in arts and learning as well as in arms." In the second place, the form of slavery known to the ancients and unknown to us is a difference that must be given great weight. The slaves were hostile captives taken in war. The proportion of the slaves to the native population was always a menace to the state, and hence their cruel treatment, and in the end brought about the nation's downfall directly or indirectly. I regret that space only allows me to indicate this difference between the ancient and modern worlds, but its tremendous importance is attested by all the leading historians. A third difference is the prominence of the military class among the ancients over the same class among us. War and conquest seem to have been the principal business of the ancients, for reasons obvious enough to any thoughtful person; barbarous nations had to be quelled; ambitious autocrats had to settle personal quarrels with neighboring autocrats; the great standing armies had to be kept employed; and the mass of the people had to gain a livelihood, which, in those days of comparatively less commercial industry, was most easily obtained in the army. Arrogance, pride, discontent, and sensuality naturally crept into those victorious armies during their periods of enforced idleness. Later on these armies became mercenary, full of internal dissension, void of all patriotism, and antagonistic to the very

people they were supposed to serve. The treachery and rebellious spirit of the Prætorians, that shattered the throne of the Cæsars and their vast empire, was but a repetition of what had already occurred in the kingdoms of Assyria, Persia, Egypt, and Macedonia. A chapter might be written on this difference—the military difference, if I may be allowed the expression—between those nations and ours. On the military side, the patriotism of the American people is a stronger bulwark against national calamity than were the mighty legions of Rome. It was the growing patriotism that once threw the mercenaries of the short-sighted Bourbons at the time of the French Revolution. This revolution, with all its horrors, was a blessing to France and the French people, and I cannot comprehend how Dr. Weir regards it in the same light as the downfall of the Roman Empire and of the Egyptian and Babylonian civilizations They were due to entirely different causes—causes most apparent in each case, local in time and place and not at all present or operative in our republican nation. A rotten monarchy, a crushing and privileged aristocracy, and a servile army cannot justly be compared with a free republic and a patriotic, prosperous, independent people. A fourth difference between the ancient and modern worlds is that of government. Assyria and Egypt and even the Roman Empire were more autocratic in their form of government than modern Russia. Russia to-day, however, is gradually climbing to the standard which America has set before the world, which France has already adopted, which England has adopted all but in name and which other nations are showing a strong disposition to adopt, namely, the government of a people for a people by a people. The ancient monarchies fell when the autocrats which ruled them fell. They were self-destructive by reason of their form of government. It was the degeneracy of their masters, more than that of their people, that crushed Assyria, Egypt, and Rome. Our rulers, however, are the people themselves, and to apply the argument to us, we could only expect the immediate downfall of our nation by presupposing that our people were degenerate.

This brings me to the most important criticism that I wish to make. It seems to me that we are pushing the doctrine of individual degeneracy too far these days. When a genius is thought to be a degenerate because, forsooth, he does something better than his neighbors, and when he is regarded as unbalanced because he is not content to quietly eat his three meals a day, sleep his sleep at night, and do nothing beyond the routine of the mass of his fellows, I think it is time to call a halt and to candidly ask ourselves, what is a normal man, and what are the limits of a normal man's capabilities. I have lately examined some lists of so-called degenerates tabulated by various writers, and in these lists were the names of certain intellectual giants, who, had they been alive, I fear would have been tempted to knock the tabulators down for their impertinence. Genius may be erratic and eccentric and all that, but, unless it goes beyond certain limits, it is a gratuitous insult to call it degenerate and less normal than the rest of dull mankind. Lombroso is leading us astray in his peculiar estimation of genius. If dull uniformity be the standard, let some alienist define for us the precise limitations of this delectable dulness and uniformity. For instance, of how much music must one be capable, say, before he is likely to be regarded as a genius and a degenerate? How much of poetic inspiration must a man have to keep him within the happy, fortunate class of non-degenerates? In fine, how much of science and art and invention must anyone possess before he steps over the line of insipid boredom into the doubtful arena of genius and degeneracy? Where is the line that divides the degenerate or atavistic from the non-degenerate or perfect, the abnormal genius from the normal mediocrity? Understand, I have no objection to the use of the word degenerate, though it unfortunately does convey the idea of inferiority. My dispute is solely with the drawing of the line between the normal and abnormal, as some of our alienists are now doing. Without having defined for us the normal man, they audaciously seize upon nearly all of the great ones of earth, those who have instructed and entertained mankind, and boldly label them abnormal, degenerate. They are even indicating for us the physical stigmata of degeneracy as seen in the heads and faces of these abnormal men. In one of the recent journals, there appeared a series of countenances of various criminals, fanatics, and enthusiasts, some badly drawn, and nearly all in misleading poses, and we were asked to notice that in this one the eyes were too close together, in that one too far apart; that in another the ears were too large, in yet another too small; that in some the brow was too high, in others too low; that in this man the lower maxilla was too prominent, in that girl it was too retracted. And so on through the series. After reading the article in question, I walked down State Street and began studying some of my fellow-citizens. I wondered who of them were, after all, normal men. I saw one man with eyes close together, ears a trifle large, and some other stigmata that I had just been reading about, and I marvelled that he was not arrested before he had committed some crime, for clearly he was a typical and pronounced degenerate. He bore, however, I believe, an unusually good and honest reputation! I wonder if the author of that illustrated article would feel sure enough of his stigmata to go into a crowd and with their aid pick out the probable lunatics, criminals, and individuals likely to harm society by reason of their atavistic tendencies? It seems to me this sort of reasoning is surprisingly *post hoc* rather than *propter hoc*. Until we know more about the normal man and are better able to distinguish him from the abnormal, such guess-work savors much of the old woman's "I told you so," after the accident has occurred.

Like the socialists, many of the advocates of the degeneracy doctrine would have us adopt for the standard the lowest rather than the highest. The tendency of their reasoning seems to be downward rather than upward for the normal man, and their pessimism therefore is scarcely to be wondered at. There is a suggestiveness in much of the theory as it is applied to genius of the fable of the tailless fox who tried to persuade his brethren to admire his superior gracefulness. There are degenerates, no doubt, and the subject of criminal psychology is one of the most serious that man can study, for its results will redound to the good of society; but when at this early stage of the science, it is pushed to extremes and unwarranted assumptions are made while we are yet unfamiliar with the perfect man, when genius and those who tower head and shoulders above their fellows in mental power, and when even those who, like the French Revolutionists, committed crimes under the most terrible provocations, are calmly set down as abnormal beings, degenerates, and are even declared to show their degeneracy in a few scarcely perceptible, contradictory facial stigmata such as may be often seen in the faces of many honest and honorable men, the doctrine borders close upon the ridiculous. Like a boomerang, its absurdity will recoil upon itself, intelligent men will become disgusted and a valuable practical department of science will have received a grievous setback.

As an illustration of how a man's judgment may become warped when he studies all things from the side of criminology, I would refer to some of Dr. Weir's remarks upon dancing. I quote his own words so as not to be misunderstood. "Contact of the sexes in the dance is only pleasurable because of that contact. . . . Estheticism and carnality are by no means as dissociate as the æsthete would have us believe. All pleasurable emotions that have their inception in the

senses are fundamentally of carnal origin. The waltz is æsthetic, yet all of its pleasure is based on an emotion closely akin to sensuality." If the distinguished writer really means all that his words imply, he has scandalized, I fear, many fine and noble-minded persons. I know numbers of individuals of both sexes who are as pure-minded and innocent of sensuality as an infant, that nevertheless revel in the dance when inspired by the brilliant illumination of the ball-room and the rhythmic measures of the music. I know not if the doctor be a married man, but if he is, some day perchance, he may see his little boy or girl trip the "light fantastic" to the sounds of the rhythmic waltz across his parlor floor. Will he then look upon his innocent, happy child, full of pretty activity and impelled by the sounds of the music and declare that he is doing it from a feeling of sensuality? Were the ancient religious dances, such as the Hebrew dancing before the ark, the dancing upon the return of the victorious conqueror, such as the old Greek choraic dances or even such as the wild Indian and African dances of to-day, associated with thoughts of sensuality? Any form of amusement may be degraded by the carnal-minded. There are of course lewd ballets, skirt-dances, and high kickings. But to say that so ancient, natural, and graceful an expression of one's emotions as the dance is a sensual exercise is cynicism itself and insulting to hosts of pure, refined, and cultured people. Dancing is as harmless an exercise as running and swimming. Like laughing it is one of the distinguishing differences between man and the brutes. It is as old as the human race itself and in the dim vista of antiquity it was associated with things divine. It is the rhythm of movement as music is the rhythm of sound. To him who beholds only sensuality in it, the best answer is "honi soit qui mal y pense."

Again, to say that the rich, surrounded with luxury, are fast becoming debauched, and that insanity is rapidly on the increase seem to me to be great exaggerations. Close intermarrying has had more to do with the degeneration of the European aristocracy, cited by the author, than luxury; while in this country anyone who has mingled in the slightest degree with its best society, with all its wealth and luxury, will bear witness to the fact that corruption is not coextensive with it. Many a mansion in our American cities is the centre of as charming a domestic circle as is the humblest cotter's thatch. The prominence of the wealthy class naturally gives more prominence to the peccadilloes that occur in their midst than to those which occur amid the poorer class. It is rank cant to prate about the debauchery and licentiousness among Americans that happen to be wealthy and capable of enjoying the luxuries of this life. It savors too much of the speech of the demagogue. Debauchery and licentiousness have existed from the beginning of the world; they have raised their ugly hydra heads time and again and have as often been firmly suppressed. They are, however, as indigenous, if not more so, in the East End as in the West End.

And, as to the increase of insanity, it is stated upon good authority that there is only an apparent increase. Being at last recognized as a disease and not as a kind of witchcraft, a pitiable misfortune rather than a burning shame, families are now more free to send their afflicted ones to the asylums than they were in the past. Furthermore, in milder cases of insanity, better diagnoses are being made to-day, which obviously tends to prevalence and apparent increase. But the very thing that induces Dr. Weir to draw his melancholy prognosis seems to me to indicate a brighter and better outlook. Science has taught alienists a superior treatment of mental affections; better asylums and hospitals are now being erected and in every possible way better care is afforded these unfortunate creatures. One of the many proofs of this fact is the readiness with which families now send their insane members to these modern institutions. Men always seek the best. The apparent increase of insanity which so alarms our author is, if anything, an evidence of a larger knowledge and a kindlier humanity on our part. Just as the flocking of a group of children about one man and their avoidance of another reveals a kindlier disposition on the part of the former, so the apparent increase in the number of the insane coming before public notice gives evidence of a higher skill and a nobler civilization in our midst.

The doctor again points gloomily to our modern licentious literature and adduces it as a proof of our degeneracy. He quotes a couple of works as illustrations. I seriously question, however, whether "His Private Character" has enjoyed the popularity of "Marcella," or whether "Is This Your Son, My Lord?" is known to half as many people as is "Ben-Hur." The signs of the times show an early extinction of this intensely realistic school of literature, the coarse school of Zola.

Good sense is prevailing, and a new and more wholesome literature is already springing up in our midst. Nasty realism in romance was only exotic at best, and never did have any firm root. Its beginning decay already proves that the race is still guided by pure and noble sentiments. But how can Dr. Weir speak of this literature having any real influence and quote two books little heard of among the better class of readers when he recalls the popularity of such writers as Howells, Stevenson, Doyle, Wallace, Ward, Stockton, and a host of others, too many for me to mention here?

Is it, indeed, a sign of disaster and of an early "social cataclysm" when such splendid work is being done as has just been done in New York by the Lexow Committee, and which promises to be done here in Chicago by the Civic Federation? How soon will it not be before New Orleans and St. Louis and other cities will take up the needed reform? But, alas! our author again views these splendid achievements in the cause of reform and purity from the opposite stand-point. He sees the corruption that has been unearthed, the fraud that has been wiped out, and at once he concludes that because all this sin existed the nation is full of rottenness, and a "social cataclysm" is near at hand. Is it not more true rather that these sins have existed always among men, and that the rising of the people to blot them out of existence as they are now doing, or trying to do, shows that they are still a strong healthful people, full of a sturdy good sense and yet far from degeneracy and extinction.

Yes, I am glad I see through other glasses than does Dr. Weir. With our vast uncultivated territory, our countless industries, our extensive commerce, our railroads and telegraph, our marvellous inventions, our growing art, science, and literature, with our splendid achievements in surgery, naval architecture and engineering, our great universities and charities, with our happy homes dotted all over the country, our magnificent cities, our peace with all the world, with our free and liberal form of government, our patriotism and our rich galaxy of great names, such as Washington, Lincoln, and Grant in war and statesmanship, Webster and Clay in oratory, Longfellow, Lowell, Bryant, and Emerson in literature, Powers, Greenough, and Church in art, Mason, Buck, and Paine in music, Gray, Edison, and others in electricity and mechanics—with all this wealth, and power, and opportunity around us I am at a loss to see the signs of a near social cataclysm. Are we not in the very midst of men who are leading the world in finance, commerce, industry, art, science, literature, and invention? "Is it the beginning of the end?" Most assuredly not, else never had an end so glorious a beginning!

L. Harrison Mettler, A.M., M.D.

"HEAR THE OTHER SIDE."

To the Editor of the Medical Record.

Sir: A writer like the author of the article "Is it the Beginning of the End?" always speaks of society in a very limited sense. He seems to think that any change in the existing state of civilization must be a change for the worse, or rather must tend toward the destruction of society. Mankind is continually advancing; and society, that is the relations of men to each other, must likewise change. The form which is suitable for one stage of progress is not suitable for another; and to alter the form is not to destroy society, or even to threaten it, but is, so to speak, merely the development of the shell at the same rate as that of the kernel. Civilization must ever travel the road of progress or stagnate, and stagnation is degeneration. There are those who believe that the growth and perfection of machinery has so changed the possibilities of production and distribution, has so broadened our social horizon, so increased the chances for a better civilization, that a radical change in the form of society is imperatively demanded, and, in fact must irresistibly come, either by peaceful change or violent revolution. And they believe that this alteration may be brought about by the former method, if people will be reasonable, open their eyes to plain facts, and apply sufficient remedies where they see wrongs and inconsistencies. Those who are of this opinion, and who believe in the public ownership of the means of production, distribution, and exchange are Socialists. Dr. Weir says they are degenerates—the offspring of luxury and vice, the scions of unnatural and degraded passions. He gives no reasons for this remarkable statement.

According to this prophet of woe, during the coming "social cataclysm . . . beside which the French Revolution will sink into utter insignificance . . . they [the ultra rich] will simply open their purses . . . and pay for the privilege of being protected. The sober middle class is a business people, and they will demand and obtain assistance from their wealthy brethren." That is to say, that even in the awful times of the social revolution, the guiding star of the middle class will be "business." They will protect the ultra rich from the just consequences of their folly, provided they pay high enough for their protection. It is, apparently, to be a union of the "effeminate, sensual, and luxurious" ultra rich with their brethren, the "sober middle class" against the "army of degenerates, composed of anarchists, socialists, nihilists, sexual perverts, and congenital criminals." Now sexual perverts and congenital criminals are, of course, degenerates. Anarchists may be. Nihilists is a term applicable only to Russia, to perverts and congenital criminals. As to Socialists, I question very much whether the author knows what they really do believe, or that he has any information on the subject worthy of the name. Does he class among degenerates such names as John Stuart Mill, Thomas Carlyle, John Ruskin, Tolstoi, Karl Marx, William Morris, Sidney Webb, Horace Greeley, W. D. Howells, Arthur Sherburne Hardy, or Edward Bellamy? Does he know that their writings are full of Socialism? That Mill, in his "Autobiography," avowed himself a Socialist; or that John Ruskin, in "Fors Clavigera" called himself a "Communist of the old school—reddest also of the red?" Does he know that some of the leading political economists of this country believe in the national or municipal control of "natural" monopolies, which is incomplete Socialism?

And who are the "great middle class" which is to save civilization—and incidentally get paid for it by "demanding assistance" from their wealthy brethren? I have no figures for this country (being an ordinary workingman, poverty-stricken, and, therefore, degenerate, I have no encyclopædia), but, in the *Century Magazine* for December, 1892, is an article by Washington Gladden, on "The Problem of Poverty," in which are given some authoritative figures for the city of London. Here we find that, of the total of 4,209,170 inhabitants of the central districts of the metropolis, 37,610, or nine per cent., are classed as lowest, which would include most of the congenital criminals; 316,834, or 7.5 per cent., very poor, who are in chronic want; 938,293, or 22.3 per cent., poor, "who barely manage to keep the wolf from the door;" 2,166,503, or 51.5 per cent., working-class, regularly employed and fairly comfortable: 749,930, or 17.8 per cent., middle class and above. Where is the "great middle class" which is to reap profit by being the "true conservators of society?" And this 750,000 includes the higher (?) class as well.

The complicated organism called society never for a moment stands still. It is constantly growing. The danger comes, not from Socialists, but from those who, like Dr. Weir, would dam up the river of progress, causing its onward flow to cease for a time, but breaking out shortly with irresistible force, and sweeping all before it, good and bad. It is not the calm, onward flow of the river which causes any harm, which is, on the contrary, of the greatest benefit, but the mad attempt to fight natural laws, which causes destruction.

C. W. Cavanaugh.

New York, January 12, 1895.

THE TELEPHONE PROBE.

To the Editor of the Medical Record.

Sir: The improvement, described by Dr. Wells, of the Navy, for Dr. Girdner's telephone probe, recalls to mind the experiments made by myself in 1890. I used for a time a small battery, but found that the battery as such could be eliminated; its place being supplied by two dissimilar metals which on moist contact yield a current something like the .000001 part of a Leclanché cell, but which is sufficient to give a very loud and distinct sound when the circuit is completed; of course this is a battery, but it is the most durable and the least expensive imaginable.

In the *Medical and Surgical Reporter* of May 31, 1890, I described the instrument, which has since been put on the market by Leach & Green of Boston.

The probe proper consists of a flexible cannula containing two insulated wires, the ends of which project a short distance beyond the cannula.

To the handle of the telephone are fastened at opposite points a zinc and copper plate which are connected in the circuit exactly as the two poles of a battery; all connections being made in the handle of the instrument are of course invisible; by grasping the handle of the telephone with the hand a current is generated, due to the contact of the two dissimilar metals, and whenever this current is "made" or "broken," the characteristic clicking sound is heard in the instrument.

As will be seen by reference to the illustration, I do not use the body at all as a conductor, but have the two terminals concealed in the probe; the current being completed by the exposed ends coming in contact with the bullet.

This method of eliminating the body as a conductor, is a distinct feature, for the resistance of the body to a current is very variable. But if Dr. Girdner's probe is used and found too weak, I suggest that two plates be connected in the circuit as in my probe. I know from experiment that this will amply increase the current without the expense and trouble of a special battery.

West Fairview, Pa.

Statues to American Medical Men.—A correspondent of the *American Journal of the Medical Sciences* says that for years there has been a statue of Dr. J. D. Crawford in the Rotunda at Washington.

THE MARRIAGE OF SYPHILITICS.

To the Editor of the Medical Record.

Sir: I have received, from all parts of the United States, letters from prominent physicians and college professors giving statistics of third generation inherited syphilis, since the appearance of my article in the Medical Record of December 15, 1894.

I now request all readers of the Medical Record who may feel so inclined and can give statistics substantiating the ground I have taken against the marriage of syphilitics and in favor of pure marriages, and the betterment of the race by confining syphilis among its own class, and out of the sacred homes of America, to write me personal letters giving any facts and cases at their command, and I will endeavor to furnish a later paper with more complete statistics.

I am fully convinced something must be done to stamp out the disease. I believe proper legislation, supported by the State Board of Health, could be enacted which would confine it among its kind, and that there it will exterminate itself and its kind.

Frank E. Maine, M.D.

Auburn, N. Y., January 4, 1895.

THE DANGER OF CIRCUMCISION.

To the Editor of the Medical Record.

Sir: While looking up the official records of the New York Board of Health in reference to the number of deaths reported due to circumcision, my attention was called to a report of Dr. R. H. Taylor. In 1872 Dr. A. Jacobi called the attention of the City Sanitary Inspector to a case of syphilis in an infant; he suspected that this disease was transmitted to the baby by the mohel-surgeon while performing the operation of circumcision. Dr. Taylor was then requested to investigate this case. Three similar cases were seen by the same physician within the same year. Of those four cases three died, the fourth, yielding to antisyphilitic treatment, ultimately recovered. Though Dr. Taylor could not assure himself at that time of the fact that this poison was directly communicated to the infants by the mohel, as the latter did not present the symptoms of syphilis on his person, nor give any history of the disease, he was positive that the malady attacked the infants during the operation of circumcision.[1] The conclusions and suggestions of Dr. Taylor in his report are in the same line with those I had the honor to present in my paper in the Medical Record, though his are less radical—due, I believe, to the fact that the mortality of infants following circumcision twenty-two years ago, was small in comparison with that, commencing in 1881, when the Hebrew population of New York City began to increase greatly.

Circumcision as a cause of death is recorded in the report of the Board of Health sixty-seven times in the years 1881 to 1894, inclusive. I believe these figures speak for themselves, and go to support the view taken in my paper, recommending the interference of the medical profession and the local boards of health in behalf of our innocent babies.

A few words of acknowledgment are yet due to my kind critic, Dr. Hochlerner. Probably, the shortest and most instructive reply to all his sweeping statements would be: "Look, investigate, and think," but this would hardly be the most courteous one. Dr. Hochlerner calls circumcision "a little procedure," and not operation, when all the text-books of the world and the boards of health put that little procedure under the general heading of surgical operations. He also believes that "complication after circumcision so grave as to cause death is so unheard of . . . it is infinitestimally small." One would suppose he based that belief on some absolute grounds, because he unhesitatingly continues: "Let the Board of Health statistics (which he certainly never consulted) answer, how often do they contain reports of deaths as the result of circumcision?" To this assertion I must say: "Look to the above figures and convince yourself." My critic ventures to say that "in the best modern hospitals sepsis occurs a hundredfold more than in that crowded little room. In which hospitals? Where? On what facts is this statement based? I believe it would suffice to refer Dr. Hocklerner to the reports of the New York Maternity Hospital, for instance, from which he could learn that in that modern institution the mortality due to sepsis is very small indeed. Referring to the short time circumcision consumes in the hands of an experienced mohel, I must state that time has never been considered a factor in producing sepsis, but unclean instruments and dirty hands and fingernails always cause mischief. Being anxious to exclude circumcision from the category of surgical operations, he tries to lower its professional dignity by comparing it with vaccination. But the records of the Board of Health will again show that the operation of vaccination has been the cause of many deaths. Dr. Hochlerner must have been exceptionally fortunate to have had the opportunity (within less than two years in a country place) to witness dozens of times the country mohel's armamentarium, not complete without a bottle of carbolic and iodoform gauze."

Neither time nor space permits me to continue these arguments, but in conclusion I must say that my learned critic has misunderstood the idea expressed in my paper. I advocate interference not with the rite of circumcision, but with the methods used in this operation, and indirectly causing avoidable deaths.

Henry Levien, M.D.

239 East Broadway.

[1] Report of Dr. Taylor to City Sanitary Inspector, New York, April, 1873.

To the Editor of the Medical Record.

Sir: Dr. Hochlerner's article on circumcision, in which he would like to prove that circumcision is as well performed by the Jewish mohel as by physicians, in my opinion is based upon one-sided prejudice.

He states that the mohel is such an expert at the operation that no evil results follow it. This statement I must deny, because it came under my personal notice that part of the glans penis was cut off; in another where too much of the fore-skin was taken off; and recently one in which a piece of the scrotum about the size of a half-dollar was missing. This would either show that they were such experts that they became careless, or they did not know how to perform the operation properly—which latter theory seems to be the most probable one to me.

In regard to hemorrhage, the practitioners on the East Side of New York are often called in by the mohels at a time when the child is losing a great amount of blood and has become weakened thereby. My learned colleague states that the record of the mohel in regard to septics is so small, that the great surgeons would be proud to possess such. In my experience the knowledge of antiseptics of the mohel is very small, and they even seem to ridicule the idea of using them; although they do not expose the wound to the open air very long, but instead they tie it up with a dirty piece of rag or linen which is constantly in contact with the wound, and so more dangerous than mere exposure to air. In one case a mohel, who seemed to be a little more intelligent than the rest I came in contact with, used the urine of the child both as a styptic and antiseptic lotion. Their hands and instruments are not antiseptic, they suck off the blood, by which they bring in contact with the wound, the saliva or perhaps their decayed teeth, which may be syphilitic or covered by tobacco-juice. Gangrene and erysipelas may complicate it.

He cites the Board of Health statistics, that the mortality of children after the operation by a mohel is practically nil; but this only shows, as he himself

states, that it is no more of an operation than vaccination, and that when any complication arises, the physician is called in, and by his scientific treatment saves the bad record of the mohel. But vaccination itself is entirely in the hands of the physician. I have no doubt that the record of an unexperienced physician would be better than that of an experienced mohel.

The religious rite has nothing to do with the circumcision itself, which they can perform if they want to; but I honestly believe that the operation should be performed by the physician only.

Yours respectfully,

MARTIN SCHWARTZ, M.D.

334 EAST FOURTH STREET, December 19, 1894.

ANÆSTHESIA BY ETHYL BROMIDE AND CHLOROFORM.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the November 3, 1894, number of the MEDICAL RECORD, you published an editorial on "Anæsthesia by Ethyl Bromide and Chloroform," referring to Dr. Magill's "New and Rapid Method of Anæsthesia."

Dr. Magill first published a notice of this paper in the MEDICAL RECORD of October 21, 1893, and I answered his communication on November 18, 1893, disputing his claims. He wrote again in your issue of January 13, 1894, denying the validity of my proofs, and I answered in the issue of February 3, 1894, and my last letter has remained unanswered, so that I infer he admits the correctness of my statements. I clearly showed that the same methods which he claimed as new were used and reported[1] ten or more years before Dr. Magill's report of them.

Why Dr. Magill persists in claiming priority in these methods I know not, but I think it but just to the men who originally described the methods that, since his paper has been editorially noted by you, their priority should also receive notice from you in your official capacity, especially as his claims were successfully refuted in your own journal.

Leaving the justice of my plea to your judgment, and hoping to see "Honor given to whom honor is due," I am,

Yours fraternally,

J. TORRANCE RUGH, M.D.

PHILADELPHIA, PA., December 20, 1894.

IS MALARIA A WATER-BORNE DISEASE?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In replying to Dr. Daly's letter of September 15, 1894, under the above heading, I stated that my experience was that we could and did contract malaria through the air-passages, and that water was also a means by which it was transmitted. Dr. Daly positively states that it can only be taken in through the food-channels, and in his first letter, September 15, 1894, he states that many will say that his position is untenable (something which cannot be maintained or supported). I am one of the many, and when I used the word "absurd" when the Doctor says that New Yorkers take in their malaria on turnip-tops, cabbage, kale, spinach, I certainly did not mean it in any other sense than that given by Webster (inconsistent with reason); for I claimed that the vegetables mentioned were boiled before eating, and surely, if merely washing the leaves with clean water before using will destroy the malarial deposit as the doctor states, why then the doctor's theory is "inconsistent with reason." By the way I notice that, since I called the doctor's attention to the fact that the above-mentioned vegetables were usually cooked before eating, he has selected celery, lettuce, and radishes as the New Yorkers' malarial "bête noire."

I am asked to answer eight questions as to the water-supply of this place: percentage of people who drink it; number of men (Italians all) who had malaria while working in the sewer-ditch which caused the outbreak; milk-supply—and all this for the information of the medical profession. As the majority of medical men believe as I do, it is not fair for the doctor to represent himself other than as an individual. However, for his information I will say that the water-supply is from springs in the uplands having a fall of one hundred and eighty feet to every thirty-four thousand feet; ninety-five per cent. of the people drink it; the milk comes from everywhere in the county, the celery, lettuce, and radishes grow on all sorts of land. Italians don't run to doctors with malaria (subacute), the season prior to the ditch-opening was dry.

I do not agree with Dr. Daly, that water is the only source of malarial infection. I do not question his long experience, accurate, and original investigation; but I say that his field and time have been limited in comparison with others; and as he prohibits the mentioning of well-known names of a few years back, I will only call his attention to Crudeli, 1892, where he still points out that the poison of malaria is inherent in the soil of certain localities, that it is excited to fresh activity by all measures involving the disturbance of the earth, especially that which has long been quiescent. Flint's "Practice," 1886, page 1001, gives all that Dr. Daly gives as to the progress made to discover the parasitic organism in this disease.

As a peace-offering for not seeing as Dr. Daly does, I am pleased to tell him that Dr. Bartley, of Brooklyn, claims to have succeeded in demonstrating the presence of malarial organisms in the public water-supply of that city.

F. W. DALRYMPLE, M.D.

NEW ROCHELLE, N. Y.

THE OCCURRENCE OF APPENDICITIS DURING PREGNANCY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the MEDICAL RECORD of December 1, 1894, Dr. Paul F. Mundé, in his paper entitled "Premature Delivery of a Dead Child induced by Acute Appendicitis, with Remarks on Appendicitis in Women," makes the following statement: "So far as I am aware there is no case on record of appendicitis during pregnancy." I beg leave to call the doctor's attention to such a case, reported by myself in the MEDICAL RECORD of January 23, 1892, page 109.

FREDERICK HOLME WIGGIN, M.D.

55 WEST THIRTY-SIXTH STREET, NEW YORK.

THE SIN OF SUBSTITUTION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Whether it is that I am more unfortunately situated than others in respect to honest druggists, or whether it is that others suffer equally with me and are either ignorant of the wrong done them, or are more patient in their long-suffering, I cannot say. I do, however, know that the injury done me and my patients by the grasping disposition and dishonest methods of some compounders of drugs, makes an excuse for addressing you, and seeking through you the aid of the MEDICAL RECORD in devising some plan by which the evil of substituting some other drug for the one ordered may be corrected.

Besides the downright robbery of filling with acetanilid a prescription calling for antipyrin, we have to contend with the misplaced conscientiousness which prompts the "honest" druggist to withhold from the mixture a poisonous drug, "for fear the physician is giving too much." Then there is the progressive chemist, who always has a pepsin, or a coca wine, or a beef, wine, and iron of his own, which is so far superior to

[1] Ethyl Bromide and Ether in August 7, 1880, and Ethyl Bromide and Chloroform, in October, 1883.

the one you order that he feels called upon to tell all your patients of it. This putting in of something "just as good or better," has reached a point in some places which tempts the doctor to dispense his own medicines entirely, and thus dispense with the local druggist known to thus abuse his position.

Hoping some plan can be hit upon to bring the offender to terms, I am, respectfully,

A Victim of the Wily Druggist.
S. M. T.

Dover, January 20, 1895.

WHAT IS MEANT BY "USUAL TREATMENT?"

To the Editor of the Medical Record.

Sir: In your issue of January 5, 1895, there appeared a very well written article on Nervous Dyspepsia, by H. Illoway, M.D. I read it with great interest and was delighted with the prospects of obtaining such brilliant and rapid results as the author pictured, in a condition generally regarded as exceedingly rebellious to treatment. All the cases reported by the doctor received what he termed his "usual treatment," and I read on, confidently expecting to learn what this was, but to my great disappointment the subject of treatment was omitted and the article ended with the address of the writer, instead of the word "continued." I must confess that I am consumed with curiosity to know how such happy results were obtained, and my object in writing is to ask Dr. Illoway, through the columns of your valuable journal, to kindly divulge what his "usual treatment" is, and thereby benefit all who are interested in this line of work.

Alpheus Freeman, M.D.

123 East Seventy-fourth Street, New York.

CASTIGATION FOR CRIME.

To the Editor of the Medical Record.

Sir: In the last issue of your Journal, in referring to the subject of corporal punishment for certain forms of crime, you state: ". . . and Dr. E. H. Grandin also favored the measure, the latter advocating emasculation for lustful crimes." This statement, appearing without the balance of my remarks, places me in a much more rabid light than I am entitled to shine in, and magnifies greatly the intent of my words. Mr. Gerry, in his remarks, specified a number of horrible instances of rape and of incest committed on infants, the punishment of which is, at best, a few years in the penitentiary. I questioned if such a penal measure acted as a deterrent to others, or indeed could possibly reform brutes capable of such actions. I took the ground that individuals capable of such horrible atrocities had likely enough passed the boundary line between the sane and the insane; that in the penitentiary they would find opportunity for sodomy; that the result of incarceration would be a gain in strength, flesh, and passion, so that on being set at liberty at the very first opportunity rape and incest would again be resorted to. I next stated that I was well aware that bodily mutilation could not in these days of high civilization be resorted to, but that I questioned if the whipping-post would do any good; that, indeed, such a punishment by no means was adequate to the crime, and that the only feasible way, short of incarceration for life, of dealing with these brutes was to so mutilate them as to deprive them of the power of committing the acts by removing not only the testicles but also the penis. The crimes referred to are hardly met by the term "lustful."

Such is the exact ground I stand upon, and I know that all who were present and heard the details of the awful crimes against the person of infants in this city of New York felt that incarceration and the whipping-post would never cure the brutes guilty of the acts, for the reason that they must be placed in the category of the insane. If they are to be allowed to walk the streets at all, they should be deprived of the ability—to refer to an actual fact—of splitting the pelvic floor of a child of six by means of the penis of a full-grown brute.

Yours respectfully,
Egbert H. Grandin, M.D.

36 East Fifty-eighth Street, New York.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 19, 1895.

	Cases.	Deaths.
Tuberculosis	134	105
Typhoid fever	6	2
Scarlet fever	93	17
Cerebro-spinal meningitis	0	2
Measles	82	9
Diphtheria	185	33
Small-pox	3	1

Decrease in the Death-rate.—The bulletin of the New York State Board of Health for the month of October shows that the reported mortality for the month has decreased from a daily average of 311 to one of 290, which is identical with that of the corresponding month of last year. The average daily death-rate for the preceding nine months was 335. The death-rate per thousand population annually was about 16.60, against 17.50 in September, and 19.15 in August. In one hundred and fifty cities and villages, representing seventy-five per cent. of the population, the death-rate was 17.75, against 18.85 in September, showing a material decrease in the urban mortality. In six large cities there were about two hundred fewer deaths than in September. There was a proportionate reduction in the rural mortality, the reported deaths from the same sparsely populated towns being 250 fewer than in September. The infant mortality was greatly reduced, the number of deaths under five years being 1,000 less than in September. From zymotic diseases there were 1,420 deaths, against 2,320 in September, and 1,540 in October, 1893. Eighteen per cent. of the total mortality was from these causes, against an average for this month for ten years of nineteen. There were 800 fewer deaths from diarrhœal diseases than in September. The mortality was, however, up to the average for the month. The customary fall increase from diphtheria, which did not show itself in September, has appeared, having caused 170 more deaths, but the mortality is a little less than a year ago. The increase is confined to the large cities. From typhoid fever the number of deaths has not increased. Scarlet fever continues but lightly prevalent, and caused but 32 deaths. There was an increase of nearly two hundred and fifty deaths from acute respiratory diseases, as is usual. Consumption caused 1,012 deaths, or very nearly the average for the nine months preceding.

A Country without a Dispensary System.—There being no dispensary "system" in France, the medical relief of the poor is as complicated as it is cumbersome. There is a lamentable want of organization, and the inefficiency is so patent that the Municipal Council contemplates recasting the old and effete machinery. The cause is simply due to the rooted dislike the French have for anything approaching "pauperism." That wounds their *amour propre;* they have the thing, but reject the name. The French send the aged, the in-

firm, and the incurable to the hospice, the seriously sick to the hospital. Then a line is sharply drawn between the indigent and the necessitous, who are assisted through what are called the *Bureaux de Bienfaisance* or Relief Boards. The latter operate in two manners, give succor in food and medicaments to those who must come to the establishment, and next to those at their domiciles.—*Medical Press.*

Coca as a Tipple has, we fear, come to stay, at least until its deleterious effects are better known. Coca wine alone, or with brandy, is among the drinks which infest the American bar. A cocaine habit can be easily acquired by the use of coca wine. It is a serious question whether our Boards of Health or legislative bodies should not pay some attention to the matter. If coca wine is allowed, why not poppy wine or a hashish wine?

A Large Gall-stone.—Dr. T. A. McGraw reports in the *Medical Age* a case of intestinal obstruction which was found on operation to be caused by a gall-stone completely filling the lumen of the intestine, at the junction of the jejunum and ileum. The calculus weighed two hundred and fifty grains.

"Curiosities of a Country Practice."—The writer of an article under this title, which appears in the November number of the *Cornhill Magazine*, is a medical practitioner in Cornwall, and gives some curious and most interesting examples of the survival in his district of strange superstitions. A few years ago a white witch —"a dirty old woman living in a back street—the repository of innumerable absurdities handed down from countless generations of traffic in the black art"—shared with the orthodox practitioner the confidence of the country folk. The wise woman under her different names may, we know, be found in many parts of England yet, though her functions are generally more those of the soothsayer, of the astrologer, or of the detective, than of the physician, but it is hard to believe that such a remedy as the one that follows—a remedy redolent of Alexander of Tralles—could really have been proposed in England in the year of the Jubilee. Yet as late as 1887, the finger of a man who had committed suicide by hanging was used to charm away epileptic fits! A story is also told of how and why a woman preserved in spirit a toe which had been amputated, and the view taken by the patient shows in a wonderfully vivid manner how inextricably the materialistic and the transcendental are mixed in all vulgar superstitions. She had lived a bad life, she said, and she did not know where the toe might go if she allowed it to be buried at once; but as she had resolved to lead a more creditable career in the future she kept the lost member by her, "that she might get her toe again some day and not go limping in the next world." The article is, in fact, an amusing collection of suggestive stories. The dates are not given, and this deficiency makes it impossible for us to see whether the fairy story confirms or refutes Mr. Andrew Lang's theory on the extinction of fairies, as given in his new "Yellow Fairy Book;" but, with sufficient proof appended to render them trustworthy contributions to a science, many of the episodes described in "Curiosities of a Country Practice" would be welcome additions to the archives of folk-lore.—*Lancet.*

The German Obstetrical Position.—German women are uniformly delivered in the dorsal position, and it seems never to occur to them or their medical attendants to try any other posture. Dr. Mensinga, of Flensburg, in Holstein, calls attention to the following experience: Having occasion to perform podalic version in a woman with a somewhat narrow vagina, he found that by placing her in a prone position, with the thorax and the upper part of the abdomen resting on a pillow, he could very easily grasp the fœtal knees, which it had before been quite impossible for him to reach. Version was then easy to perform, and the fœtus was extracted readily. In fact, Dr. Mensinga says the condition of the perineum up to the anus, during the passage of the child's head, can be observed by this method with an accuracy of which he had before had no idea, although, as I may mention, in parenthesis, he is not by any means a young man, but has been engaged a lifetime in gynecological practice.

Anecdote of Sir William Gull.—Sir George Johnson tells the editor of the *British Medical Journal*, that Sir William Gull, whom he met at Eastbourne shortly before his death, said to him, "You know the true translation of Γνῶθι σεαυτόν is, 'Test your urine.'" The editor remarks that it would be interesting to know whether this had been done within a year or two in the case of the late Czar. The following note from *Le Progrès Médical* for November gives an answer which is interesting, if true:

THE CZAR'S ILLNESS.—The medical profession of St. Petersburg, according to *Le Temps*, accuses Professor Zacharin of having neglected to ascertain the state of the late Czar's kidneys after his attack of influenza of last year. The surgeon of the imperial yacht Polar Star, while the imperial family were cruising last year along the coast of Finland, noticed that the Czar had œdema of the face. He secretly secured a specimen of his majesty's urine from a servant, analyzed it, and found evidence of advanced disease of the kidneys. He informed the court physician, Dr. Hirsch, of his discovery, and the latter having confirmed the diagnosis by his own examination, ordered immediate return to dry land, and residence in a dry climate.

Prize of the American Neurological Association.—The American Neurological Association offers a prize of $200 for the best essay on any subject connected with neurological science. This competition is open to physicians who are legal residents of states in North and South America. Essays must be sent to the Secretary of the Association on or before May 10, 1895. Each essay shall be accompanied by a sealed envelope containing the name and address of the author, and bearing on the outside a motto, which shall also be inscribed upon the essay. Essays shall be type-written, in either the English or French languages, and with the pages securely fastened. The Council of the Association reserves the right to reject any or all essays judged unworthy of the award. Each essay must exhibit original research, and none will be accepted that has previously been published. Græme M. Hammond, M.D., *Secretary*, 58 West Forty-fifth Street, New York City.

Divers Statutes for Pharmacists.—The *British and Colonial Druggist* has been making a study of the pharmacy laws prevailing in the different States and Territories, and publishes the following summary:

In the following all must undergo the State's examination: Washington, Mississippi, Nebraska, Ohio, Illinois, Rhode Island, Massachusetts, Michigan, Minnesota, New York, Wisconsin, Arkansas, Maine, New Jersey, Pennsylvania, Utah, West Virginia.

The following accept graduates of regular colleges of pharmacy: Florida, District of Columbia, Iowa, Missouri, Oklahoma.

Georgia.—This State accepts the certificates of Germany, France, Great Britain, Ireland, and Ontario. All others must submit to examination, but are allowed to practice until the regular meeting of the Board, provided they hold a certificate.

Virginia accepts the certificates of Great Britain and Ireland, but a bill is before the State Legislature which will render examination compulsory.

Louisiana accepts no pharmacy certificates. Pharmaceutical graduates of foreign universities are, however, recognized.

Wyoming.—The pharmacy law is a dead letter.

North Dakota will register persons if the board be satisfied as to their standing and character.

Oregon accepts the English and Irish certificates.

Texas.—There is no State board, but a separate board for each judicial district, and each board determines for itself what certificates will be accepted for registration.

Idaho.—No State board. Each county decides as to what certificates it will accept.

California accepts all certificates where four years' experience is required, and attendance at two or more courses of lectures.

North Carolina recognizes the Ontario certificate, and would consider any other certificates submitted and decide on their merits.

Kings County, N. Y., will accept the higher diploma of any teaching school of pharmacy in any country.

Baltimore.—The city of Baltimore admits persons holding diplomas from recognized colleges of pharmacy, based upon a full four years' apprenticeship as a pharmacist. All other persons wishing to practise must be examined.—*Bulletin of Pharmacy.*

A Royal Ancestress.—A princess of Roumania has recently been born, who makes the nineteenth great grandchild of Queen Victoria. *The Lancet* makes the auspicious occasion the text for a few loyally affectionate remarks upon the family tie, the joys of maternity, the emancipation of woman, the education of children, and various subjects with which the queen has had to do. "No one," says our contemporary, "can better appreciate the true purport and value of the family tie than our justly respected Sovereign. Her character and conduct have always tended to confirm its strength as a social force in this country. There is consequently a peculiar and beautiful fitness in the fact that her Majesty's domestic bond, long since formed, and afterward rudely severed by death, has proved through many succeeding strains fruitful in the happiness of home and children's love. We hear much daily of the freedom and the dignity of a new womanhood, which has for its object other and supposed worthier aims than the claims of maternity. We will not dispute the value and utility of some of these. We would be the last, however, to assert the superiority of their votaries to many women who can understand and fairly gauge the indispensable position of their sex in home life. The royal ancestress of sixty direct descendants, placed or to be placed in stations of responsibility, is, we doubt not, wisely cognizant of the high qualities necessary to a parent to secure the proper training of her children. Her own example has shown that the performance of this duty is not incompatible with other social or official functions."

A Slight Mistake.—This is an instance where a bad cold caused a startling conversation. A modest young newspaper man was invited to a party at a residence where the home had recently been blessed with an addition to the family. Accompanied by his best girl he met his hostess at the door, and after customary salutations asked after the baby. The lady was suffering from a severe cold, which made her slightly deaf, and she mistakenly supposed that the young man was inquiring about her cold. She replied that though she usually had one every winter this was the worst she had ever had ; it kept her awake at night a good deal at first and confined her to her bed. Then noticing that the scribe was becoming pale and nervous, she said that she could see by his looks that he was going to have one just like hers and asked him if he wished to lie down. The paper came out as usual the next week, but the editor has given up inquiring about babies.

Bacilli in Street-cars.—Experiments recently made by Dr. Ezra Wilson, bacteriologist of the Brooklyn Health Department, demonstrate the presence of bacilli in the dust and sweeping of the street-cars in that city. He has reported a fatal case of tuberculosis in a guinea-pig which had been inoculated with bacilli cultivated from dried sputum found in the cars. Health Commissioner Emory has decided, as a means of disinfecting the stations and cars of that city, that they shall be thoroughly cleansed every three days with a solution of bichloride of mercury. A sub-committee on the Prevention of Tuberculosis, of the Medical Society of the County of Kings recently recommended that a city ordinance be passed making it a misdemeanor to expectorate in any public conveyance, but the suggestion was not carried out.—*New York Medical Journal.*

Diminishing Birth-rates.—During recent years the birth-rate per thousand population has been diminishing in proportion to population in most civilized countries, as will be seen by the following table :

Country	1880	1890
United States	36.0	30.7
England and Wales	34.2	30.2
Scotland	33.6	30.3
Ireland	24.7	22.3
France	24.5	21.8
Belgium	31.1	28.7
German Empire	37.6	35.7
Austria	38.0	36.7
Switzerland	29.6	26.6
Denmark	31.8	30.6
Norway	30.7	30.0
Netherlands	35.5	32.9

Dr. W. Xavier Cudduth thinks that great singers have large antra, and draws the following conclusions from his study of the subject (*Journal of the American Medical Association*) : That the maxillary sinuses are developed with the growth of the individual after birth. That in some instances one or both are absent or but slightly developed. That they have no definite form and vary greatly as to size in different individuals. That there is a correspondence between the breadth of the face and the size of the antra. That in some instances they are divided into compartments by osseous walls, which effect resonance. That they are cavities intimately connected with the nasal fossæ, being separated therefrom, in part at least, by a thin membranous partition. That the air contained in these cavities vibrates in harmony with the tones produced by the vocal cords. That this vibration is most appreciable when the tones produced are full of melody, as in certain kinds of church music and negro melodies. That it is more prominent in singing than in speaking, unless a special declamatory effort is attempted. That there is a type of individual to which the successful vocalist and orator belongs, and which is indicated, among other things, by a considerable but harmonious development of the maxillary sinuses. That variation in the size and shape of the resonant cavities, when present, undoubtedly affects their value as resonators ; and finally, that certain races, noted for their melodious voices, are distinguished for the conformity of their physiognomy to the type above given for vocalists.

Sewer-Air and Diphtheria.—A correspondent of *The Lancet* writes that a year or two ago a new system of main sewerage with the ordinary road-level ventilators was inaugurated in one of the suburbs of London, and upon its being brought into use serious cases of diphtheria almost immediately began to break out. The medical officer of health at once had the drains flushed with a strong solution of perchloride of mercury, and the cases then stopped almost as quickly as they commenced.

The Mitchell District Medical Society held its forty-sixth semi-annual meeting at Mitchell, Ind., on December 27th and 28th, 1894. The programme was an attractive one, and many physicians from Cincinnati, Chicago, St. Louis, Louisville, Indianapolis, and other cities in the States bordering upon Indiana read papers.

THE INFLUENCE OF THE BICYCLE IN HEALTH AND IN DISEASE.[1]

By GRÆME M. HAMMOND, M.D.,

NEW YORK.

PROFESSOR OF DISEASES OF THE MIND AND NERVOUS SYSTEM IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; PROFESSOR OF MENTAL AND NERVOUS DISEASES IN THE UNIVERSITY OF VERMONT.

ABOUT two years ago I called attention to the treatment of certain diseases of the nervous system by the proper use of the bicycle.[2] This was the first attempt, at least in this country, to call the attention of the medical profession to a therapeutic agent undoubtedly of great value. At that time comparatively few physicians had had any practical experience with the bicycle, but since then wheeling has taken hold of the popular fancy to such an extent that thousands now ride where formerly hundreds rode, and the medical man who at one time considered bicycle riding degrading to his professional dignity, now joins with his lay brothers in the pursuit of health and pleasure on the wheel. The universal popularity of the wheel—and it seems to be growing in favor every year—has undoubtedly not only been a source of great pleasure to thousands, but must also have had an appreciable effect upon the health, either beneficially or the reverse, and physicians are now arriving at a more intelligent conception of the possibilities of the wheel, both for good and for evil. The medical journals of this and foreign countries are daily adding to the literature of the subject by the reports of diseases which seem to have been induced or are aggravated by the use of the wheel.

The question concerning the deleterious effect on the human organism by the injudicious use of the wheel concerns the numerous specialists in medicine as well as the general practitioner. There is hardly an organ in the body which may not be influenced one way or the other by the proper or improper use of the bicycle; and hence it is that all medical men should study this question carefully and endeavor to arrive at the exact facts of the case. To this purpose I propose to consider the subject from the following stand-points: 1. The use of the cycle by persons in health. 2. The use of the cycle by persons diseased.

Little need be said about the rational use of the bicycle by healthy persons. It is only when the wheel is improperly or immoderately used that it constitutes a source of danger. The question will at once arise as to what constitutes this moderate and rational use. As men differ, among other things, in points of age, temperament, physical strength, and power of endurance, so is it absolutely impossible to prescribe any general rule which will be applicable to all men. Each individual must formulate rules for his own guidance, and if he is incapable of doing this either because he has not arrived at years of discretion, or because he recognizes his ignorance and distrusts his judgment, his medical adviser should be consulted, who by studying his physique, heart measurement, and lung capacity, can judge with considerable accuracy the amount of exercise which is most conducive to healthy physical development. But as a general rule, the average individual after a fair amount of experience, becomes quite competent to determine his own capabilities and requirements.

Let it be granted that an individual uses the wheel properly, what results should he reasonably expect to achieve? Statistics do not supply any information on this subject. No attempt has as yet been made, that I am aware of, to study the physical development of men who have been using the bicycle properly for years. I say for years, because the best effects of any form of exercise which is practised for the purpose of obtaining physical development, are never obtained rapidly and, particularly in young subjects, should only be studied after several years of continuous culture. There being no available literature on the subject, I am obliged to depend solely upon my own observations. This source of information must necessarily be very meagre. Although there are thousands who ride, there are comparatively few within my reach who have been riding long enough to render statistics on their physical development of much value. I have, however, collected fourteen cases of amateur riders who have kept accurate records of the years they have been riding, and approximate records of the number of miles they have ridden in this time. These cases I have examined and endeavored to tabulate the most important features ascertained. These men have ridden from five to thirteen years, and in that time have travelled from five thousand miles to twenty-seven thousand miles.

TABLE NO. 1.

Amateur Riders.

Cases.	Age.	Ridden a Wheel. Years.	Miles Ridden.	Chest Expansion. Inches.	Heart.	Muscular System.
1....	37	5	22,000	1¾	Slight hypertrophy	Well developed.
2....	25	10	27,000	1¾	" "	Legs well developed, arms and trunk fair.
3....	36	5	8,000	2	" "	General development greatly beyond normal
4....	42	12	24,000	1½	" "	Well developed.
5 ...	46	13	25,000	1	Normal.	Average.
6 ..	24	13	14,000	1⅞	Slight hypertrophy.	Well developed.
7 ...	25	10	20,000	1¾	" "	" "
8 ...	34	7	18,000	1⅝	" "	" "
9...	30	8	9,000	1⅜	Normal.	" "
10...	29	7	8,000	1⅞	Slight hypertrophy	" "
11....	26	7	17,000	2	" "	Generally very muscular.
12 ..	24	6	7,000	1¼	Normal.	Average.
13....	39	5	6,000	1⅛	"	"
14....	24	5	5,000	1½	Slight hypertrophy.	Well developed.

Average chest expansion, 1⅝ inch. Heart usually hypertrophied without dilatation. Average age, 31⅘ years. Chest expansion, 13 riders above normal; 1 normal.

This table demonstrates two important facts very clearly. First, that men who have ridden a great deal for a number of years have acquired simple cardiac hypertrophy without dilatation; and second, that their breathing capacity is greatly in excess of that of the average man. The cardiac hypertrophy that I refer to is due to a simple increase of muscular tissue, and is in the nature of a healthy growth or development induced by exercise. It is precisely similar to the hypertrophy which occurs in any other muscle which has been used a great deal. Hypertrophy in this sense is purely a

[1] Read before the New York Academy of Medicine, December 19, 1894.

[2] Journal of Nervous and Mental Diseases, January, 1892.

relative term. For more than a century man has shown a tendency to develop the different qualities of the mind, and has paid but little attention to the gradual degeneration of the muscular system and to the consequential reduction of his powers of physical endurance. This has been one of the natural consequences of the rapid advance of civilization, especially in this country, and this, together with the great development of industries, commerce, and the professions, which have demanded the best energies of our men, finally made us a race of intelligent, clear-sighted, energetic, and nervous people, but very far short of the physical perfection seen in men in earlier ages. The dangers attending this physical degeneration of the race have of late years been gradually instilled into the public mind, and this has resulted in a healthful reaction. Men, and, what is of almost equal importance, women, are gradually beginning to comprehend the advantages of physical development, and are in a fair way to understand that the highest type of man, taken as a whole, is not represented by intellectuality alone, but more properly by a judicious combination of mental and physical vigor. Ten or fifteen years ago it was exceptional to find business and professional men and women who practised any special form of exercise. To-day thousands are making physical exercise an important feature of their daily duties; and what is of greater importance, we are educating our children to believe in physical culture and to practise it. The evolution of the bicycle to the form it presents to-day is probably the greatest factor which has influenced the spread of the doctrine of physical culture in this century. As a natural consequence of this gradual but universal physical development, which will only be attained in time, we must expect to observe a relative development of some of the internal organs, particularly of the heart and lungs. The simple hypertrophy of the heart observed in most bicycle riders who have ridden to any extent, will gradually become more common, and finally will be accepted as normal, and what is known to-day as the normal heart will then be considered degenerated.

A second glance at the table shows that all the riders have a greater breathing capacity than the average man. The chest of the average man expands an inch when the lungs are inflated to their greatest capacity. This has been carefully verified by myself and by others, who have measured many men whose lung-powers have not been developed by special forms of exercise. It is usually believed that the average chest-expansion is three inches, and there are many who can increase the girth of the chest much more than this. It is claimed, for instance, that Sandow's expansion is thirteen inches. This, however, is fallacious and does not by any means express the truth. It is accomplished by a forced expiration before the inspiration, and is then further augmented by "setting" the scapular and pectoral muscles. In the table I have prepared the average lung inflation is represented by a chest expansion of one and four-sevenths of an inch, which is an excess of four-sevenths of an inch above that of the average man.

This excess is unquestionably of great advantage to the individual possessing it, when it is taken into consideration what a great influence is exerted on the general health and on the proper performance of the functions of the various organs by a perfect oxygenization of the blood: and when there is added to this the action of a powerful, muscular heart, it can readily be perceived that bicycle riding, conducted properly and for a long time, induces a condition of cardiac and pulmonary development which must exert an enormous influence in maintaining the proper functions of other organs; in preparing the organism to resist disease; and in overcoming disease that has been contracted.

The muscular system of the bicycle rider is, as a rule, uniformly well developed. It is often claimed by those who are not properly informed, that the exercise develops the muscles of the legs at the expense of the rest of the body. This is not so. On the contrary, the muscles of the back, chest, arms, and abdomen are employed a great deal—not to the same extent as the muscles of the legs, but sufficiently so to consider bicycle riding an exercise inducing general development of the muscular system.

The observations recorded in Table No. 1 were made on men who have always ridden in the erect posture. A great deal has been said in regard to the pernicious effects of riding with the body almost, if not quite, at a right angle with the legs. A peculiar malformation of the spine has been reported to result from this posture, and it certainly seems as if the lungs, and consequently the heart, must be greatly hampered in performing their work. To obtain some information on this subject I have carefully examined fourteen professional riders, seven of whom are the most celebrated racing men in the world—men who have obtained national reputations as great riders; who have ridden more races than any other men; and who have ridden faster than any other men; and who always ride with the body at right angles to the legs. These observations I have tabulated in Table No. 2. In no case was there any deformity of the spinal column, and I may say here, if any such condition has ever been observed, the number of cases of it must be very few indeed. I have never seen a case of it. They were all well-built, muscular men, but differed from those in Table No. 1, who were all amateurs, in that in all cases there was an excessive development, compared to the rest of the body, of the muscles of the thighs, particularly of the *vastus internus* and of the muscles of the abdomen.

TABLE NO. 2.

Professional Riders.

Names.	Age.	Remarks.	Chest Expansion. Inches.	Heart.	Muscular System.
Zimmermann	24	American world's champion.	1¾	Hypertrophied.	Well developed. Extraordinary development of abdominal and thigh muscles.
Wheeler	25	American. Celebrated rider.	1⅞	"	Well developed. Extraordinary development of abdominal and thigh muscles.
Edwards	23	England's champion.	1⅞	"	Well developed. Extraordinary development of abdominal and thigh muscles.
Verheyn	20	Germany's champion.	1½	Slight hypertrophy.	Well developed. Extraordinary development of abdominal and thigh muscles.
Colombo	23	Italy's champion.	2	Slight hypertrophy.	Very muscular. No special development.
Lesna	31	France's 24-hour champion.	2	Slight hypertrophy.	Very muscular. No special development.
Martin	25	America's 6-days champion.	2	Hypertrophied.	Very muscular, especially in the thighs.
Albert	28	American. 6 days rider and short distance racer.	1½	"	Too slender for his height. Muscles not at all prominent except in abdomen.
Berlo	28	American. Short distance racer.	¾	Hypertrophied, but not strong.	Muscular thighs and abdomen. Chest somewhat sunken.
Knowles	40	American. 6,240 miles in 60 days racer.	¾	Hypertrophied.	Very muscular.
Foster	40	German. Long distance rider.	¾	"	Normal development.
Gross	28	American. Short distance racer.	1	"	Well developed.
Murphy, W. F.	25	American. Class B racer.	¾	Hypertrophied, but not strong.	Not at all muscular except in thighs and abdomen.
Macdonald	18	American. Class B racer.	1¾	Normal and very strong.	Small but well developed.

Average age, 27 years. Average chest expansion, 1⅜ inch. Chest expansion, 9 above normal (these are celebrated riders); 1 normal (1 inch); 4 below normal.

The development of the abdominal muscles resulted from their continual contraction while maintaining the

riders in their racing position. All had cardiac hypertrophy without dilatation. At first glance it would seem as if the lung capacity of the professionals was fully as good as that of the amateurs, and this is true if the measurements of the national champions only are considered.

Table No. 2 gives the measurements of fourteen celebrated professional riders. Table No. 1 gives the same measurements in an equal number of amateurs. Comparing the measurements of amateur riders with those of the professionals, who are national champions, very little difference can be observed. These men who ride at racing speed, doubled up like a jack-knife, were as well developed, had just as powerful and healthy hearts, and their lungs could consume as much oxygen as those who sat upright and rode at moderate speed. But it must not be concluded from this that I mean to infer that *any* man can race and ride in the posture of a racer with impunity. Far from it. These men became professionals because they found that nature had particularly adapted them for fast riding. They make a business of it, and are always in the best possible physical condition.

If we turn, however, to the measurements of the other six professionals, whose inferior capabilities have not allowed them to become national celebrities, we find a very different state of affairs. One has the normal chest expansion of one inch, four below normal, and one is above normal. The latter, however, has been racing but a short time, having recently graduated from the amateur ranks. Comparing the fourteen amateur riders with the fourteen professionals, it will be seen that the average chest expansion of the amateurs is $1\frac{4}{7}$ of an inch, while that of the professionals is $1\frac{3}{7}$ of an inch. The expansion of thirteen amateurs is above normal, and in one it is normal. With the professionals the expansion is above normal in eight, normal in one, and below normal in four. It is quite probable, if professional riders of less phenomenal abilities were substituted in the second table in place of the national champions, the average chest expansion would be found to be below normal.

Excessive work on the wheel is, for the average man, unquestionably injurious, and it seems a fair inference to draw, from a study of these cases, that while many men will, in the course of time, ascertain that nature has adapted them so they may race with impunity, for a time at least, others who are led to emulate their example will certainly injure their health and undermine their constitution. This is particularly true of young lads, many of whom consider themselves the coming racing champions of the world. They can be seen in the streets and on the country roads, tearing along at the top of their speed, the body thrown forward, the back humped and the arms fixed and rigid, the chest necessarily contracted and preventing its proper expansion, at the very time when free movement of the chest walls is most necessary. In such cases healthy development is likely to be arrested, and cardiac dilatation, impoverishment of the blood, and lowered vitality of the system are probable consequences. Parents and physicians should use their authority to prevent this abuse in the rising generation, and a youth who will not ride properly should not be allowed to ride at all. It has been claimed that appendicitis can be sometimes attributed to this faulty position in riding. While it is undoubtedly true that persons who ride the wheel, no matter in what posture they ride, may have appendicitis, there is nothing in literature to prove any direct relation between appendicitis and bicycle riding as a cause and effect.

Riding great distances at rapid speed is an abuse of the wheel which cannot be too severely condemned. Anyone who witnessed the last six days bicycle race about a year ago, cannot but recall with disgust the sickening exhibition of exhausted riders, having to be lifted from and onto their wheels and carried to and from their quarters, their joints swollen and inflamed, barely able to see, and only kept in a conscious condition by the united efforts of trainers and physicians. This, however, is an extreme case, but it is not at all uncommon for large parties of riders of both sexes to go on what are called "Century runs," that is, to ride a hundred miles often within a limited number of hours. To many riders of experience, who are in good condition and possess excellent powers of endurance, this may not be a difficult feat to perform, but many others in making the attempt suffer from exhaustion which leaves its traces for several days. There are others again, who travel shorter distances, but who ride at such speed that they return home thoroughly tired out. This, if it occurs only occasionally, is perhaps of little moment, but when the repetition is frequent it is undoubtedly injurious.

Moderate exercise, properly performed, invigorates the system, strengthens the muscles, and increases the powers of physical endurance, but excessive and exhaustive exercise does none of these things; on the contrary, it is decidedly injurious to health and should never be encouraged. Under certain conditions diseases of the genito-urinary tract may with great probability either be induced, or else, if they already exist, they may be aggravated. Cases of prostatitis, urethritis, and cystitis have been reported, which seem to show quite conclusively that the friction or jolting of the perineum against the saddle was the exciting or aggravating cause. Such cases are due to the carelessness or ignorance of the rider. An individual in riding the cycle, just as in riding the horse, should sit upon the gluteal muscles and not upon the perineum. All bicycle saddles can be tilted either forward or backward, and every person who rides should so adjust the saddle that the weight of the body is borne by the gluteal muscles and not by the perineum, otherwise it is quite probable that injurious results may follow. In regard to the excitation of the genital organs in both sexes, I am quite confident that this never occurs, unless it is done purposely or else by the greatest negligence. A woman who wishes to obtain friction of her genitals on the wheel can easily do so by adjusting her saddle for that purpose. But if she does so her position will be so uncomfortable as to deprive riding of all enjoyment. She may ride for the purpose of obtaining genital irritation, or she may ride with perfectly proper motives, but she cannot do both at the same time.

In the male the case is different. Riding upon the perineum may in many instances cause genital irritation, but this can be effectually prevented by the proper adjustment of the saddle. It can therefore be seen that these diseases or conditions are by no means necessary consequences of bicycle riding. On the contrary, they can be remedied in all cases by the intelligent comprehension of the wrong and its remedy.

The question is often asked, shall women suffering from abnormal conditions of the uterus and ovaries ride a wheel? I was much pleased, at a recent meeting of the Gynecological Section of the Academy, to listen to the opinions of our leading gynecologists on the subject. It seemed to be the general opinion that this form of exercise was not only not injurious, but that in many cases of disease it was highly beneficial, either as a means of relieving local congestion, or else acting indirectly on the pelvic organs by improving the general health of the patient.

There is one other condition which deserves mention, and which I am not aware has called forth any comment up to the present time, and that is the effect of bicycle riding on the air-passages and as a cause of mouth-breathing. On examination I found all of the men enumerated in table No. 2, and who were professional riders, breathed through the mouth while riding, and that eight of these were habitual mouth-breathers. The majority of the amateur riders I have questioned on this subject admit that they breathe through the mouth

while riding, but whether the proportion of mouth-breathers is greater among cycle riders than among those who do not ride, I do not know, but it is a matter that deserves investigation.

The use of the wheel by persons diseased, when considered in the light of a therapeutic agent, is a subject of considerable importance. It also leads us to inquire whether there are not physical conditions under which the bicycle should be absolutely prohibited. In certain diseased conditions of the heart, bicycle riding may prove very beneficial. In simple degenerated conditions of the muscular fibres, in dilated hearts either with or without compensatory hypertrophy, and in slight valvular affections, bicycle riding, when properly practised, may prove of great service, because it improves the nutrition of the organ and develops the muscular fibres, thereby enabling the heart to perform its work more effectually. But no one suffering from any cardiac affection should ever ride a wheel, unless advised to do so by his physician; and in such instances the physician should make frequent examinations in order to determine whether benefit is being derived from it or not. Where exercise is advisable in heart affections, I know of no better method of obtaining it than by the proper use of the wheel. By riding slowly and on an approximately flat surface the mildest cardiac exercise can be obtained, and this, as the heart improves in strength, can be increased by degrees, and in direct ratio with the cardiac development. By this means the strength of the heart can be greatly increased, thus causing a natural compensation for many abnormal conditions.

But bicycle riding can cause as well as cure cardiac degenerations. If an individual compels his heart to work beyond its capacity and the abuse becomes in any sense continuous, the danger of cardiac degeneration becomes imminent. This is more particularly liable to occur in subjects whose cardiac muscular fibres are abnormally weakened from disease, dissipation, or from long neglect of such exercises as are requisite for maintaining the heart in a healthy condition. In valvular lesions also immoderate riding will unquestionably aggravate existing abnormal conditions, and perhaps superimpose another cardiac disease upon the original one. In short, it may be said that bicycle riding may benefit or injure the heart according to the condition of the heart and the manner in which the individual conducts his exercise, and the general principle may be adduced that, while the moderate use of the wheel is conducive to cardial development, the excessive use endangers cardiac degeneration. I cannot agree with the decision of the French Academy, that "no one should ride a wheel without consulting a physician;" but this rule certainly should apply to all persons who have cardiac disease and to all others whose general health, vitality, and physical strength are to any degree below the normal. What has just been said in relation to cardiac diseases applies in the main to pulmonary affections. I have already shown, as far as the limited number of cases at my disposal permit, that bicycle riding, when practised by a healthy person, unquestionably develops the lungs and increases their capacity greatly beyond what is now considered to be normal. The knowledge of this fact may be taken advantage of in the treatment of those pulmonary conditions in which a breaking down of tissue will be the natural and probable consequence in the course of time. Moderate exercise of the lungs by the moderate use of the wheel practised systematically and for a long time, will undoubtedly retard and perhaps completely arrest some degenerative changes in the lungs. This will follow not only from the direct effect of pulmonary development, but also from the generally improved physical condition which is always a prominent feature of bicycle riding when rationally practised. On the other hand, I can conceive of nothing which will be more injurious to certain abnormal pulmonary conditions than the excessive use of the wheel. Not only will this tend to accelerate degenerative processes, but it may also induce them in persons predisposed, particularly if the general vitality is simultaneously diminished.

The same general rule can be formulated here that seemed to be applicable to the heart, that is: That the moderate and proper use of the wheel results in pulmonary development, while the excessive use may be followed by injurious consequences.

In my former paper I showed, by the report of a number of cases, that in certain diseases of the nervous system bicycle riding was very serviceable. That report referred mainly to cases of functional and organic paralysis, and to neurasthenia and hysteria, and demonstrated that in these conditions great improvement was obtained directly from the use of the wheel. My opinions were so fully expressed at that time that it is needless to refer to the subject again, except to state that my experience in the past two years, since that paper was published, fully corroborates the views I then entertained. I only desire to state in addition that I have carefully studied the effects of bicycle riding on numerous cases of functional dyspepsia and constipation, and have observed great benefit in most instances, but only in those cases in which the riding was followed systematically. There are two other conditions I desire to refer to before I conclude what I have to say, in which bicycle riding seems to exert a beneficial influence. These are gout and diabetes. Possibly both of these diseases are benefited by the great quantity of oxygen consumed; by the improvement in digestion and assimilation; and by the effect that prolonged muscular action has on eliminating certain substances from the system which are either poisonous *per se*, or else become so by conversion. In two cases of subacute gout I have prescribed the use of the wheel and have every reason to feel satisfied with the results. In only two cases of diabetes have I had the opportunity of making observations in regard to the effect of this exercise on the excretion of sugar. These few cases are not sufficient to allow the presentation of any absolute deductions, but the results obtained were sufficiently encouraging to warrant further investigations in this direction. If we accept the view that the manifestations of gout depend upon an excessive formation of uric acid in the system, it can be readily understood, theoretically at least, how bicycle riding can modify or arrest this process. First, by the improvement in digestion and assimilation; second, by the greater demand upon the nitrogenous compounds required by the repair of the muscles; third, by the increased oxygenation of the blood which increases the elimination of urates; and fourth, by the further elimination of morbid material through the increased activity of the sweat-glands.

This theory may be susceptible to criticism, but whether it is correct or whether we must look further for the reasons, the fact remains that benefit is derived in these cases from the use of the wheel. In the two cases of diabetes, experimental studies showed that in both cases, and with no change of diet, the amount of sugar excreted was diminished when the bicycle was used regularly. The explanation of this fact seems to be reasonable, and is similar to that just offered in reference to gout. The waste taking place in the muscles is repaired from the nitrogenous elements, which otherwise would be converted into urea and then into sugar. The larger the muscles are that are wasted, the greater quantity of nitrogenous substance will be required to complete repair. The largest muscles in the body are in the lower extremities, and consequently bicycle riding, which calls these muscles into active use better than any other form of exercise, operates to excellent advantage. The heart also need not be exercised unduly, which, in these cases, is often a point of considerable importance. It is impossible, in an article on this subject, to enter deeply into the discussion of each one of the subjects touched upon without making a paper

of interminable length. I will therefore conclude what I have to say by the statement, that experience has shown me that bicycle riding for a healthy individual is one of the most excellent forms of exercise for maintaining health, retarding disease, and strengthening the constitution, and is also a pleasant recreation for the mind; and that in many forms of disease, when used cautiously and under medical supervision, it will often be found of inestimable advantage.

THE VALUE OF THE MODERN DIAGNOSTIC METHODS IN DISEASES OF THE STOMACH.[1]

By MORRIS MANGES, A.M., M.D.,

ASSISTANT VISITING PHYSICIAN TO MOUNT SINAI HOSPITAL; LECTURER ON GENERAL MEDICINE AT THE NEW YORK POLYCLINIC.

In opening the discussion to-night, I would at the very outset state that in the short space of time allowed me it will be possible to take but a cursory glance at the wide field of the modern diagnosis of the diseases of the stomach.

With the exception of bacteriology, no other branch of medicine has witnessed such rapid progress. The advances in the last ten to fifteen years are the direct result of the introduction of the stomach-tube. In fact before the days of Kussmaul and Leube most of what was known about gastric digestion was based upon observations made upon the few bearers of fistulæ, like Alexis St. Martin. A problem which only fifty years ago seemed impossible of solution to even so shrewd an observer as Frerichs, has been cleared up by the employment of the stomach-tube and the various test-meals. With such simple means we can, with very little discomfort, evacuate the stomach at almost any time we choose, and we are thus enabled to study the processes of gastric digestion at our will.

To follow up so promising a lead was but natural; and soon a vast array of observations attested the diligence with which these studies were pursued. It was an age of chemical enthusiasm in which all the refinements of organic chemistry were employed to discover subtle tests for determining the various values of hydrochloric acid in all its combinations. To such an extreme did this movement go, that Bunge claimed as the result of comparative chemical tests in various animals that the stomach's principal function was to secrete enough hydrochloric acid to keep its contents sterile. Then, again, gastric diseases were classified according to the variations in the amount of hydrochloric acid, a method which, as Ewald properly says, is as unphilosophical as that which formerly grouped diseases into those with and without jaundice, dropsy, etc. Another manifestation of this spirit is seen in the declaration of Martius, that he would treat no case of gastric disorder unless the patient were willing to submit to a routine examination of the stomach-contents, the only exceptions being cases of weak heart and aneurism.

The statement has been repeatedly made that such examinations stand in the same relation to gastric diseases as urinary analyses do to the various forms of nephritis. Against this I wish to enter a most vigorous protest. Routine stomach-analyses do not occupy such a position, and even were they a hundred times more delicate than they now are, not even then would they do so. Were the functions of the stomach as relatively simple as those of the kidney, this comparison might hold. But the most cursory examination of the structure and innervation of the stomach ought at once to reveal the fallacy of such a claim. The stomach is the centre of a plexus the ramifications of which extend directly or indirectly to nearly all the important organs of the body. The pneumogastric and sympathetic innervation of the stomach must never be overlooked in comparing it to other organs; nor should we ever forget that delicate functional changes which play so important a part in reflex dyspepsia can never be determined by chemical analyses, not even the most complicated.

In other words, I believe it to be an error to employ the tube indiscriminately in every case presenting gastric symptoms. To quote the words of Boas,[1] its use ought to be restricted to such cases in which the symptoms render a diagnosis uncertain or impossible. It is contra-indicated where its introduction would be accompanied with some danger to the patient, as in advanced cardiac and pulmonary diseases, aneurism, pregnancy, old age, cachexia, gastric ulcer, broken-down cancers, etc., or where the other symptoms alone will permit a positive diagnosis.

I have purposely laid stress on this point, for in our enthusiasm for so valuable an aid as the tube many old and well-tried methods have unjustly been neglected. Among these is inspection. This should begin in the mouth. The condition of the teeth and gums afford as much, at times more, information than does the tongue. Dentists have taught us a very valuable lesson in showing that changes in the gums may be among the earliest symptoms of serious constitutional disorders. So valuable a prognostic aid ought not to be neglected.

Still more important is inspection of the abdomen. How much may be gained by this simple means has been shown by Osler in his recent lectures on abdominal tumors. In ten out of thirteen cases of dilatation of the stomach, the diagnosis was made by inspection alone.[2] I would also direct your attention to increased peristaltic action of the stomach, a sign revealed by inspection, but one which is very frequently overlooked. When present, a careful examination of the motility of the stomach ought to be made, for it signifies either a neurosis, an obstruction at the pylorus, or a displacement of the stomach. When the waves are very active in the latter two conditions, the shape of the stomach is often very distinctly outlined upon the abdominal parietes.

The main object of the physical examination of the stomach is the determination of its size and situation, as well as the palpation of tumors. The great abundance of methods for the former is proof that none of them is perfect. To obtain satisfactory results we must employ several of them. Succussion is very unreliable, and great care must be taken to differentiate it from that arising in the transverse colon; while percussion of the undistended stomach leads to many errors. These latter may be prevented by inflation either by generating carbonic-acid gas *in situ*, or by pumping in air through the stomach-tube by means of a double bulb. Still another means is to distend the colon with water. In the former method we employ one drachm each of sodium bicarbonate and tartaric acid, each salt being separately dissolved in half a goblet of water, the one being swallowed after the other. An ordinary Seidlitz powder may also be used. Ziemssen recommends larger quantities. I believe, with Osler, that in the majority of cases this method is preferable to the pumping in of air, since it does not require the introduction of the stomach-tube. Nevertheless, the latter method is the more accurate, and should always be employed when the results obtained with CO_2 are unsatisfactory, as occurs in very large stomachs, or where we wish to supplement the inflation by pumping in water to ascertain the exact capacity of the stomach.

In drawing inferences from the latter we must never forget the great differences which exist, normally, in

[1] Read before the New York County Medical Society, December 24, 1894.

[1] Diagnostik und Therapie der Magenkrankheiten, 3te Auflage, Band I., p. 90.

[2] Lectures on Diagnosis of Abdominal Tumors, New York Medical Journal, p. 163, October 10, 1894.

different individuals, in the size of their stomachs, and that an organ which is considered dilated in the one would be normal in another person.[1] Another source of error in this test is the varying ability of patients to retain quantities of fluid or air large enough to distend the gastric walls to their full capacity. Nor must we imagine, even if the size and situation of the stomach are ascertained, that we necessarily know its capacity for work, for I would also remind you that many writers, such as Rosenbach, Schreiber, Naunyn, Bouchard, Boas, and others, have demonstrated that many stomachs which are normal in size and situation are mechanically insufficient.

Of the many other tests for determining the situation of the stomach I shall only allude to Einhorn's gastrodiaphane. This instrument consists of a small incandescent lamp which is attached to the end of a stomach-tube. The patient having swallowed one or two glasses of water, the instrument is introduced and the current turned on. A reddish illuminated area, of various shape and size, is seen normally upon the abdomen, unless the patient is too stout. From my own experience I can say that the method is both simple and valuable; but it would be advantageous if a uniform and larger quantity of water were always employed, and if some means could be devised to lessen the translucency of the transverse colon. This difficulty I have sought to remedy by injecting dark-colored fluids into the colon.

The instrument is also of service in detecting gastroptosis or displacement of the stomach. Normally, on deep inspiration, the stomach moves downward; with the electric lamp this is clearly shown by a downward displacement of the illuminated area. This does not occur when the stomach is displaced and is no longer in contact with the diaphragm. However, the same results may be obtained with much simpler means; as, for instance, by carefully marking on the abdomen the outlines of the distended stomach, and then noting the changes in percussion on deep inspiration. Furthermore, if the displacement is marked, the increased peristalsis will often distinctly reveal the position of both the upper and lower curvatures of the stomach.

And now to consider what diagnostic information may be obtained with the stomach-tube, the test-meals, and the various chemical procedures.

As to test-meals employed, nearly all have agreed that the best is that known as Ewald's test-breakfast, which consists of a cup of tea, without milk or sugar, or simply a cup of hot water, and a roll or one or two slices of bread. It were well if it were used in all the routine tests of the chemical functions of the stomach, both for the sake of uniformity and because it is simpler and more cleanly than any other. Should the results be unsatisfactory, we can still resort to the more complicated dinners of Leube and others, which more closely resemble what the stomach is ordinarily called upon to digest.

To obtain stomach contents for examination the method of expression ought to suffice in most cases. This consists simply in bearing down as if at stool, the increased intra-abdominal pressure causing the chyme to rise into the tube. Stripping the tube will often aid in starting the syphonage. Where this fails we may aspirate with a Politzer bag or Boas's bulb[2] or attach the tube to an aspirating bottle with a low vacuum. We ought never to rely upon the results of one meal alone, but ought, especially in doubtful cases, to make at least three trials to allow for normal variations.

Although filtration of the stomach-contents lessens the acidity somewhat, yet for practical purposes this change may be disregarded. Some experiments which I made with the centrifuge to obtain clear fluid without filtration failed, as the fats rose to the surface, while the remainder of the fluid was too thick to separate readily.

As we find them described in the text-books, the various chemical tests are far too numerous, and many are much too complicated for use in general practice. The fact that so many have been recommended shows that the ideal methods are still to be found. But few of them have escaped criticism. We might apply the same statement which has been so often heard in reference to the innumerable tests for albumin and sugar in the urine—select certain of them, make yourself master of them and leave the balance for the enthusiast and the specialist.

Those which seem to me to suffice are: Litmus paper for general acidity; Congo red and tropæolin papers for free acidity; Günzburg's phloroglucin-vanillin test for free hydrochloric acid;[1] Uffelmann's carbolate of iron test for lactic acid. For total acidity titration with decinormal soda solution with phenolphthalein as the indicator. Starch and dextrin may be tested with dilute Lugol's solution and the biuret test will show the presence of peptone. The general digestive power and the presence of pepsin may be ascertained with the trial digestion of discs of albumin.[2] The milk-curdling ferment may be readily determined by adding a few drops of stomach-contents to 10 c.c of milk and allowing it to curdle. Finally there ought to be a microscopic examination of the chyme.

Numerous as are the above tests, yet twenty minutes or even less will suffice to apply them all, provided one is equipped with the necessary apparatus and experience. For the details I would refer you to the text-books of Ewald, Boas, Rosenheim, Leo, Jacksch and others, which describe them in sufficient detail.

Excluding factors of minor importance, the object of the chemical tests is to show variations in the amount of hydrochloric and lactic acids, pepsin, and rennet. The ferments may at once be dismissed from consideration, for on careful analysis in three hundred and fifty-four patients, Bouveret found them absent only twice.

Up to a relatively short time ago the relations of hydrochloric acid were considered the touchstone of all gastric analyses. So long as the absence of hydrochloric acid was considered pathognomonic of cancer, and its excess significant of ulcer of the stomach, we may readily understand why these determinations were considered of such great value. But we have since learned that free HCl may also be absent in chronic gastritis, atrophy of the gastric mucosa, during menstruation, acute febrile diseases, severe nervous depression and also in many chronic wasting diseases such as severe anæmias, tuberculosis, Addison's disease, diabetes, cardiac lesions, etc. As well put by Rosenheim, in determining the absence of free HCl we do not, strictly speaking, diagnosticate the cancer, but the accompanying gastritis and atrophy.

In this connection Wagner's[3] researches are very interesting. He examined 216 successive patients, male and female, with chronic gastro-intestinal complaints, and failed to find free HCl in 39 of them, of whom only 6 were suffering from malignant disease of the stomach. In 12 of the 33 non-cancerous cases, the secretion was either neutral or alkaline in reaction and did not contain peptone; while in the other 21, the reaction was acid and peptones were present. Most frequently the absence of free HCl was noted in persons between twenty and thirty years of age.

Nor is the persistent absence of this acid inconsistent with many years of apparently perfect health, for quite

[1] A very instructive paper by Riegel, in the Deutsche Medicinische Wochenschrift, No. 15, 1894, distinguishes very clearly between the physiologically large stomach and that which is atonic or dilated.

[2] Boas: loc. cit., p. 128.

[1] I cannot agree with Friedenwald and Benedikt, who recently strongly urged the claims of Boas's resorcin test as being superior to that of Günzburg. Although the limits of both tests are practically the same, yet I have found the latter reagent to be more prompt and positive. On the other hand the resorcin reagent is much cheaper and keeps better.

[2] See Ewald's Diseases of the Stomach, American translation, p. 47.

[3] Vratch, No. 194. See also British Medical Journal Epitome, March 31, 1894.

a number of such cases have been reported by Ewald and others. Here the intestines act vicariously for the stomach, or we may apply Ewald's[1] discovery that peptone may be formed in the stomach even in the absence of free HCl. Finally, we must mention the anomalous cases of gastric carcinoma in which HCl may even be present in excess.

So with the question of hyperacidity. This may be demonstrated not alone in ulcers, but also in gastric neuroses, in the early stages of chronic gastritis, or it may be a normal phenomenon. There are also ulcers of the stomach in which the acidity is subnormal.

Where, then, are the absolutely diagnostic features of these tests for hydrochloric acid? Even so enthusiastic a writer as Boas[2] admits that any anomaly in the secretion of HCl, considered by itself, does not with any certainty indicate the existence of a gastric disorder. We need not be surprised at such a conclusion, for the stomach has other functions besides the secretion of HCl, among which may be mentioned the formation of ferments, the absorption of peptones, water, and salts, and the churning and expulsion of the chyme. We do not yet know with any certainty how HCl is secreted, nor are we agreed in our conceptions of the free and combined forms of this acid. On the one hand, it is absolutely wrong to assert, as has recently been done by Herschell[3] and others, that these chemical tests are superfluous, and that the acidity of the stomach contents may be inferred from that of the urine. The difficulty with all these tests lies not in the results, but in their interpretation: for it must never be forgotten that distinct pathological processes do not produce corresponding sharply defined changes in the chemism of the stomach.

Bearing this in mind, I shall now give you Boas's *résumé* of the present views as to the diagnostic significance of the variations in the amount of hydrochloric acid:[4]

1. *HCl is normal* (0.1 to 0.2 per cent. HCl).—This is either indicative of a normal condition, or at least speaks against the existence of a serious structural lesion of the stomach. In the presence of vague gastric symptoms, which may indeed result from almost every internal disease, such a result is of the greatest practical importance. Should all the symptoms point to the stomach, then the occurrence of normal acidity indicates nervous dyspepsia or some intestinal disturbance. The determination of normal acidity is of especial value in differentiating nervous dyspepsia from chronic gastritis with lessening of HCl, especially since the subjective symptoms of both are very similar. At the same time we must not forget that lessened HCl may occasionally occur also in nervous dyspepsia. Furthermore, the normal amount of HCl may not unfrequently be found in atony of the stomach.

2. *HCl is lessened* (HCl less than 0.1 per cent.).—Where this result is constant, we may suspect a subacute or chronic gastritis; yet lessening of HCl may also occur in ulcer of the stomach or duodenum, incipient carcinoma, dilatation and atony of stomach, regurgitation of bile into stomach, etc.

3. *HCl is increased* (HCl more than 0.2 per cent.).—Is most frequently symptomatic of gastric neuroses; is present in a considerable number of gastric ulcers; but this is by no means a constant occurrence. May also occur in incipient chronic gastritis or pyrosis. May also be found in an ulcer which has undergone carcinomatous degeneration, provided all the symptoms of cancer of stomach are present.

4. *HCl is absent* (inacidity).—When primary, is most frequently found in advanced chronic gastritis. Furthermore, it is of not infrequent occurrence in gastric neuroses. Differentiate the two usually by the absence of ferments in the former. Is also found in gastric cancer. The significance of this symptom may be formulated thus: *a*. In general, the positive demonstration of free HCl denotes the absence of cancer, provided the other symptoms of a neoplasm are absent (tumor, cachexia, etc.). *b*. The absence of free HCl is positively indicative of cancer when at least two other clinical symptoms of this condition are present (tumor, cachexia); there is a strong probability of this lesion when, besides the absence of HCl, we also have cachexia and the symptoms of pyloric stenosis, and no suspicion of ulcer. *c*. In the differential diagnosis between ulcer and cancer, the former is indicated if the HCl tests are positive and no tumor is palpable; while if negative, the chances are against ulcer.

5. *Where HCl is variable.*—Where the conditions of test are constant, this is strongly indicative of a neurosis.

6. In the secondary dyspepsias of phthisis, nephritis, diabetes, etc., the various tests have no diagnostic value, but may be of use in the dietetic treatment.

It is only recently that lactic acid has had any diagnostic significance, and to Boas[1] belongs the credit of having called our attention to its importance in the early diagnosis of gastric cancer. He claims that inasmuch as this acid or its salts are always present in the various test-meals which contain bread and meat, it is necessary to employ a special test-breakfast when this acid is to be estimated accurately. For this purpose he gives one to two litres of a thin oatmeal gruel, to which only some little table salt has been added. It is expressed after an hour.

To be of any significance in this and other test-meals the canary-yellow color obtained with Uffelmann's test must be very well marked, as faint yellowish discoloration may be produced by many substances, such as sugar, alcohol, phosphates, etc. Therefore to be certain we ought to apply the test to the ethereal extract of the chyme, or, still better, employ certain chemical procedures which he has proposed. The latter are much too complicated for general practice.

Boas has asserted that where a large amount of lactic acid is present and the tests for free HCl are negative, there is a strong probability that a cancer of the stomach is present. Fermentation lactic acid being the product of the lactic-acid bacillus it cannot be produced in the presence of free HCl; furthermore Boas has proven that it is either absent or present in faint traces in benign gastric affections, such as chronic gastritis, atony, dilatation, neuroses, etc. It is only formed in large amounts where there is stagnation of the stomach contents, and where free HCl is at the same time absent. He therefore asserts that where these three factors are constant, *i.e.*, absence of free HCl, stagnation of stomach contents, and the formation of large quantities of lactic acid, the diagnosis of gastric carcinoma may be made even in the absence of a palpable tumor.

These tests therefore assume great importance in the early diagnosis of this disease—in other words at the time when excision of the neoplasm, the only cure, can be radically performed. The correctness of these views has been acknowledged by Rosenheim and Bouveret, and has been demonstrated practically by Boas and his assistants in a number of cases in which such early diagnoses were made and subsequently verified. I also have records of several such cases, which I shall soon publish.

It is to be noted that Boas admits that the absence of lactic acid does not exclude a cancer, as where free HCl is present or where stagnation does not occur.

I wish to add that these diagnoses ought not to be made unless subjective symptoms are present, such as loss of weight, anorexia, etc.

Of the remaining tests we may at once dismiss those for determining the absorptive powers of the stomach, as suggested by Penzoldt and others. But little information may be gained from them except in serious changes

in the mucosa. But these conditions give so many other important signs that the tests become practically superfluous.

Far more important are the methods by which the motility or peristaltic powers of the stomach is determined. As I have already shown, among the chief functions of the stomach are the churning and expulsion of the chyme into the duodenum. Indeed Ewald has asserted that apparently perfect health may be maintained for years when the secretory activity of the stomach has ceased, provided the viscus retains its motor power. Of what avail are an abundance of HCl and pepsin unless these agents can be thoroughly incorporated with the food, and the liquefied chyme passed on into the intestines? We all know that peptone formation ceases when a certain percentage has been reached, and hence digestive activity ceases, unless these products are absorbed or evacuated into the duodenum. Not until the motor functions fail do very many gastric disorders become serious. The excessive formation of lactic acid which occurs in cancer of the stomach is due to a lessening of the gastric motility which results from the infiltration of the muscularis by the neoplasm. Furthermore, a stomach may be large and yet be competent, while, on the other hand, a small stomach may be unable to do its work. So, too, a stomach may be displaced and yet be able to churn and expel its contents. Hence the necessity, as I have already shown, of not alone knowing the size, situation, and secretory activity of the stomach, but also its motility. The tests usually employed for this purpose are the salol test, as proposed by Ewald and modified by Huber; Leube's method of ascertaining whether the stomach is empty six hours after taking his meal, or Boas's method of giving a light supper and passing the tube early the next morning, when, under normal conditions, the stomach ought to be empty.[1] For determining the peristalsis of the stomach Einhorn has recently presented his gastrograph,[2] an instrument much too complicated for general use. It must be confessed that as yet we possess no ideal methods for determining the motor functions of the stomach.

This concludes what I have to say about the positive diagnostic value of the modern methods for examining the stomach. And yet, in a negative way, they frequently have an even greater significance in the differential diagnosis of obscure cases. To cite but a single group of cases, those patients who present vague symptoms and in whom we are in doubt whether the stomach, liver, or intestines are at fault. The demonstration of a normal chemism and motility of the stomach will quite readily enable us to exclude this viscus from our consideration, or, at least, lessen the probability of its being seriously at fault.

Finally, I ought not to neglect to mention the great aid which is often afforded by the various diagnostic procedures in the medicinal and dietetic treatment. No other means at our disposal furnish such valuable information concerning the administration of acids, alkalies, and ferments, and so clearly indicate the diet which is suitable to individual cases.

The followed conclusions may be formulated:

1. The great advance in our knowledge of gastric diseases is due to the introduction of the modern technique.

2. Although the tests for free hydrochloric acid are of service in diagnosticating the various affections of the stomach, yet the results obtained are of themselves by no means absolute.

3. Too little attention has heretofore been paid to the motor functions of the stomach. A careful examination in this direction will often yield much valuable information.

4. In the absence of free hydrochloric acid and when there is stagnation of the chyme the presence of large quantities of lactic acid is significant of cancer of the stomach, provided there are general symptoms of beginning cachexia.

5. The various chemical procedures give much information in directing the therapeusis and dietetic treatment of patients.

6. The diagnostic use of the tube ought to be restricted to cases in which the subjective symptoms and course of the disease will not permit a positive diagnosis.

MEDICAL TREATMENT OF THE DISEASES OF THE STOMACH.

By A. JACOBI, M.D.,
NEW YORK.

Mr. President: In the short time you placed at my disposal I shall review the more important remedies available in gastric disorders, the principal symptoms attending them; and a few of the local affections, such as ulcer, hemorrhage, and cancer. What I have the honor of presenting, is not claimed as new, or "modern," but is offered as what I have been, and am, in the habit of recommending and employing.

Some of the abnormal conditions of the stomach depend on anomalies of distant organs. Hyperæmia and catarrh result from disorders of circulation in the chest and abdomen. Incipient pulmonary tuberculosis, chronic pleurisy, particularly the diaphragmatic form, peribronchitis, emphysema, every variety of asthma, diseases of the heart and the great blood-vessels are frequently the causes of the various forms of dyspepsia. It is these causes which require treatment and not to the same extent the gastric disorders. Thus it is that the latter may be remedied by gymnastics of the chest, or by digitalis.

Irrigation through the stomach-tube is indicated, and frequently does good, when there is protracted nausea and inflation, and the taste is sour or bitter. To continue this treatment indefinitely is not indicated, or to rely on its continuation for its moral or psychic effort is injudicious, for a neurotic patient will not be influenced more by ten irrigations than by two. On the other hand, it is true that two or three irrigations will hardly suffice sometimes to clear the cavity of all the remnants of food that may have accumulated. Cases of sarcina are particularly obstinate.

Irrigations are certainly contra-indicated in most cases of gastric ulcer, of acute gastritis, except the cases produced by poison or fermenting food, in painful and in ulcerative pharyngitis, and they ought to be made with great caution when the sound has to pass a dilated heart, a large aneurism, or an elevated or strictured œsophagus. The tube should have a double opening at its lower end, it should be soft, and must not be carried far beyond the cardia. By measuring the distance from the chin to neck and along the vertebral column down to the ninth dorsal vertebra the necessary length can be found. The tube may be moistened with warm water—vaseline and glycerine are nauseating to many—and is carried down to the œsophagus; then the patient is told to make the movement of deglutition, and repeat it when the tube reaches the level of the larynx. He must breathe regularly and hold his basin with both his own hands; 500 gm. of water, or warm alkaline water are then run in, once or several times; it is not the whole amount that will come up again, for a small part will be absorbed in the stomach, and more is apt to escape into the intestines. A slight up and down movement before withdrawal prevents the mucous membrane from being caught and torn.

Irrigations are indicated when large masses of mucus cover the interior of the stomach and separate the ingesta both from the absorbent and the secreting epithelium. In these cases chloride of sodium and carbonates act as solvents. In bad cases of chronic gastritis solutions of nitrate of silver (1 to 2,000) will do

good after warm water with carbonate of sodium (not the chloride) had preceded them; also warm water in which subnitrate of bismuth has been suspended.

Papayotin (Papain), the powder, or a five per cent. solution, digests meat. In an atonic and non-secreting stomach it is therefore an excellent aid to digestion. Such specimens of disintegrated meat and cheese I demonstrated to the State Society when ten years ago I detailed the effect of the remedy on croup membranes. My remarks on that occasion have been utilized contrary to my protest by a mercantile firm who advertise a preparation which they call papoid. How much papayotin is contained therein the gods and the firm's chemists may know. I do not, but I do know that the use of my name in the circulars is an unmitigated fraud.

Pancreatin, the ferment of the pancreas, transforms starch into dextrin and sugar, splits fat, when emulsionized in the pancreatic juice, into glycerine and acids, and peptonizes albuminoids in alkaline solution. In acids it has no such effect, indeed it is decomposed. Therefore I never comprehended what good it could do when introduced into the acid stomach.

Pepsin in water and hydrochloric acid dissolves albuminates. When the stomach furnishes none, or an insufficient quantity, for instance in anæmia, chronic tuberculosis, or scrofula, in old age, in convalescence, its medicinal administration is beneficial, inasmuch as it facilitates the digestion of nitrogeneous foods. But it is inert unless accompanied with dilute hydrochloric acid. Solutions in glycerine will keep in alcohol but a short time; therefore wines of pepsin which have been preserved a long time are liable to have but little efficacy.

Bismuth. The subcarbonate, subnitrate, salicylate, or subgallate are less appropriate in gastric catarrh than they are in other forms of subacute or chronic gastritis, and mainly in ulcer of the stomach. It is a gentle and antifermentative protection to the mucous membranes and its nerve branches. The gastric neuralgia of the anæmic, the hysteric, and the pregnant are favorably influenced by it. In the same way, besides binding hydrogen sulphide, which is a potent cause of peristalsis, it protects ulcerations of the intestines, prevents their reflex effect and relieves diarrhœa.

The merits of *nitrate of silver* have become dubious in regard to most of the claims advanced for it. It was expected to heal ulcerations and to relieve gastric pain. The main objection to its use was the fact that there is always so much sodium chloride in the stomach; that is true, but when nitrate of silver is to be used, the amount of salt in the stomach need not be larger than the physiological condition of the gastric surface requires. Therefore whoever is to take nitrate of silver must not have before taken salt in his food, and ought to have a fairly empty stomach. In that condition the mucous membrane of the stomach is as amenable to the action of the nitrate as that of the pharynx or nose. It is desirable to have a similar method of administration, or rather application, in all of these cases. Pills will certainly not be so reliable as a solution, and the dilution ought to be large enough to render the distribution of the solution over a large extent of the stomach probable. An adult may take from one-half to one grain in four ounces a day, a tablespoonful every two, or two tablespoonfuls every four hours. The smallness of the doses is no objection. The greatest dilutions, 1 to 2,000 to 5,000 are known to find their way most readily into and between the epithelia. To influence a large part or the whole extent of the stomach interior, a few grains of nitrate of silver in a pint of water may be employed for irrigation.

Charcoal, I am told, is a very disappointing drug. I do not share that opinion. It is expected to bind gas, and so it does; but this property is nearly lost when it is wet. Besides, the charcoal mostly in use with us is vegetable charcoal, while the animal preparation is known to absorb about thirty times as much as the former. I never prescribe anything but carbo-animalis. To have its full effect it ought to reach the stomach in its dry state if possible. That can in part be accomplished by giving the drug in wafers or in capsules.

Amara (bitters) are stimulants appropriate for atonic condition of the stomach, both primary and secondary, mostly in anæmia, chlorosis, and exhaustion by sexual excesses. The roots of gentian and calumba, the wood of quassia and of dandelion and Irish moss belong here. Their effect is but mild, their action by reflex on the secretion of saliva is known but not marked, that on the secretion of gastric juice is doubtful. Thus it is that they are often administered in tinctures which contain ethereal oils and alcohol, both of which are more active. The latter do not agree with acute gastric catarrh and ulceration. One of the best known, for good and evil, is cundurango. In America it began its career in 1871, in 1874 in Germany. I well remember the stir it made in the newspapers of the day. It was imported by a downtown firm from Ecuador and cured every case of cancer of the stomach. To return the compliment, the same firm exported large invoices of Scott's cancer remedy to cure the cancers of the stomachs of the people of Ecuador. Such is fraternity and solidarity. After a while, when the excitement was over, cundurango was found to be an excellent amarum. A decoction of 15 in 300, made after a maceration of twelve hours, so as to leave 150, acts quite favorably. So does the extract of cundurango, one or two grains of which may be administered five or ten times a day.

In the same direction are active other bitters and the aromatics, the mints, cardamom, caraway, cascarilla, mace, pimento, ginger, cinchona, pepper.

Most of us will prefer one, or very few, or none of the substances mentioned. When given in tinctures or in extracts, they may be combined with adjuvants and corrigents, in liquid or pill form, with quinia, iron, etc. Some of us are still fond of orexin, the indispensable cure-all, the effect of which has always appeared doubtful to me. The best of all the bitters is nux vomica; its tincture, fluid extract, solid extract, and its alkaloid permit of many ways of administration and combination, with good effect.

Rhubarb in small doses has no cathartic effect, but through its gallic acid is rather constipating. In doses of from 2 ctgr. to 2 degr. several times a day it acts favorably in chronic gastric catarrh and nausea and vomiting depending thereon. In small doses it improves the appetite, particularly in scrofulous and rickety children, when feeble digestion, or dyspepsia follows an attack of diarrhœa. The aqueous tincture of rhubarb which has been received from the German Pharmacopœia into our "National Formulary" is a good preparation. Adults take one-half to one teaspoonful after meals. Our aromatic tincture of rhubarb is a good preparation when the stimulating effect of alcohol is required.

Motory incompetency may be the result of gradual decrease of muscular strength in anæmia, slow convalescence, etc., or depend on a congenital, either general or circumscribed, insufficiency, but is mostly the outcome of a protracted catarrh and dilatation. It is quite frequently combined with insufficient secretion of gas-juice. These are the cases in which orexin has been recommended. Amara and diluted alcohol, spices, aromatics, internal douching, external douching, both cold and hot, massage, electricity, both externally and internally, appear indicated. Pepsin and hydrochloric acid are required when the secretion is more defective than the contractility.

Lack of hydrochloric acid results from defective innervation, in anæmia and convalescence, or from local causes; atrophy of the glands, cicatrices, or tumor. The secretion of pepsin is defective at the same time. Both have to be supplied in the shape of medicine.

Excess of acid, however, is more frequent. Its over-

secretion may be due to chronic gastritis, ulceration, or neurosis. In some instances it is due to a chronic dyspepsia, depending on the abuse of tobacco or of alcohol, or both. With the exception of the cases of over-acidity from ulcer which yield a local pain, that excess is characterized by a more extensive pain than is attributable to a local lesion. Whatever excites the gastric secretion must be avoided. Instead of chloride or bicarbonate of sodium, of aromatics, of acids, give nitrate of silver 1 to 3,000 to 6,000, in tablespoonful doses, also some opium. If a purgative be required, give sulphate of sodium. Not infrequently the over-secretion of hydrochloric acid accompanying the first stage of a subacute gastric catarrh gives way, in the further stage, to under-secretion. In that case the treatment of the catarrh, including irrigations, is indicated.

The treatment of ulceration will be referred to later.

The neurotic cases require slow eating to avoid suddenness of secretion, more animal food but no fat, no carbonic acid, and the treatment of the neurosis of the stomach, which will be detailed later on.

In all cases antacids are indicated, such as prepared chalk, bismuth, or magnesia, but they are liable not to have the same favorable effect as when they are given when the secretion is not of hydrochloric but of butyric acid, which is the principal and most objectionable result of undue fermentation. The presence of this acid is an obstacle to digestion and ought to be neutralized before food is taken. Magnesia must be given ten minutes before a meal in sufficient doses. Quite often the presence of this acid accompanies a chronic catarrh with insufficient gastric juice. Thus I frequently, after giving the antacid before every meal, administer pepsin and dilute hydrochloric acid toward the end of, or after it.

Round ulcer of the stomach requires, theoretically speaking, absolute rest of the stomach until the ulceration can heal. That indication cannot be filled. But the only food endured and permissible is milk, not to be drank, but eaten with a teaspoon. It ought to be boiled or sterilized, and the stomach kept alkaline. Magnesia can be taken in daily doses of two or three grammes for some time without giving rise to diarrhœa. If larger doses of alkali than the above be required, and diarrhœa be feared, bismuth may be added from two to four grammes a day, or prepared chalk, or phosphate of lime. It is desirable to take no carbonate, not even the sodium salt, in order not to inflate the stomach. The total daily amount must be given in eight or ten doses. They may be so arranged as to precede by a few minutes the meals, which ought to be small but frequent. Opiates will enforce rest, and are, in the beginning of the treatment, in doses of from 10 to 15 milligr. every two or four hours, almost indispensable. Irrigation ought to be avoided as a rule. I have many years ago irrigated with a high dilution of nitrate of silver. Bismuth subnitrate has been thus used, but instruments are dangerous inside an ulcerated stomach, and bismuth taken internally will probably cover the sore surface as well as if thrown in when suspended in water.

The vomiting and neuralgia of neurotic persons are frequently the despair of the physician. They are as curable and incurable as other symptoms of hysteria. By attending to the person you may conquer the organ. So the medicinal and hygienic armamentarium will be in pressing demand. Opiates ought to be avoided if barely possible. Cocaine has been recommended very highly; I cannot say that I have seen it doing much good. It has been customary to employ cerium oxalate, mainly, in the vomiting of pregnancy; nitrate of silver has failed me entirely in these cases. Three remedies have often aided me. One is the tincture of iodine, in half to one drop doses every one, two, or three hours, the other is arsenious acid, in doses of one-third or one-fifth of a milligramme every two or three hours, and zinc, either the valerianate from seventy-five to one hundred and twenty-five centigrammes daily in divided doses, with or without bismuth, or the oxide in four or six daily doses of from two to five centigrammes each. Menthol and alcohol, (1 to 10) applications to the præcordia have sometimes proved successful. In the vomiting of pregnacy, wine of ipecac, one drop every hour, has given satisfaction. One of the symptoms of stomach neurosis is rumination, regurgitation of part of the food taken. Though the symptom be by no means rare, I do not remember a case, in adult or children, but exhibited quite an array of neurotic symptoms. Thus general tonics, seabathing, cold ablutions and frictions, strychnia, zinc, ferri carbonas, are the remedies required. Electricity —the interrupted current—will sometimes prove effective, one electrode over the neck, the other over the epigastrium. Often the metal brush, short applications, works better than the wet sponge.

There are other cases of vomiting having their origin in distant parts. Chronic peritonitis with adhesions, will result in obstinate constipation. Now constipation, from whatever cause, is liable to give rise to obstinate vomiting, extending over many weeks, even months. I have seen them getting relieved by purgatives and rectal irrigations. Qui bene purgat bene curat.

When vomiting attends acute gastric catarrh, and is so persistent as to render both feeding and medication impossible, calomel, given in sufficient doses, will be absorbed in the mouth, and have its full effect as a purgative. Now and then leeches, ice, hot fomentations, dry cupping, may relieve the gastric congestion or irritability. When food is thrown up after being taken, a small dose of morphia on the tongue, in solution or in tablet form, five or ten minutes before eating, will make it endurable. In this way even anæmic vomiting can be moderated.

In cases of protracted fermentation in the stomach, attention must be paid to the foods and other ingesta, among the latter to the swallowed secretion of the nose and pharynx. Many a case of putrid dyspepsia can be effectually cured in the nose and mouth. Irrigation of the stomach with water, salt water, salicylic acid 1 to 1,000, thymol 1 to 2 to 3,000, or hypermanganate of potassium 1 to 2,000 will find their indications. But they cannot be employed forever, and in most cases the powers of the stomach will not be restored by them. Among the anti-fermentatives I mostly use, is dilute hydrochloric acid. Thirty or forty drops in a quart of water, will form an appropriate drink through twenty-four hours. Bismuth and its phenol combinations act very well, but not by themselves alone. Creosote in daily doses of from eight to twenty-five drops, creolin in similar doses, plentifully diluted, act very well. So does hypermanganate of potassium, 1 to 2,000, in frequent teaspoon or half tablespoonful doses. Resorcin, from seventy-five to one hundred and fifty centigrammes a day, divided into four or six doses, one to be given fifteen minutes after meals, and now and then between, mixed or not with bismuth; bicarbonate of sodium, acts very well. Calomel acts better on the intestine than on the stomach. Chlorine, iodoform, and naphthaline have been given for the disinfection of the stomach. But stomachs which require disinfection are generally too irritated and irritable to tolerate just these three. Aromatics may be given. The elæosacchara of fennel and mint have been added to the "National Formulary." They are pleasant and efficient additions to bismuth, calomel, etc., in children's ailments.

Hemorrhage.—No sounding, no irrigation. Seldom will the stomach as much as tolerate chloride of iron or acetate of lead. Besides, in the doses which can possibly be introduced, they do as little good in hemorrhages from the surface of the stomach as from another integument. Avoid the internal use of alcohol or carbonated waters; avoid even water. Ice inter-

nally may do good by contracting the stomach; its direct influence on the bleeding vessels can be but trifling. Ergot preparations may be employed under the skin. It is desirable to keep the stomach contracted by a heavy ice-bag, which acts both by its weight and its temperature. The body must be kept at rest, recumbent; if any food be permitted, that will be iced milk in small quantities. Bismuth subnitrate is probably the only thing which is both tolerated and useful. Rest can be procured both to mind and circulation through the hypodermic use of morphia.

Cancer of the stomach, both near the pylorus and on the wall of the organ, has more indications than successes. We shall hear to-night of what surgery feels like doing, and in quite a number of instances has succeeded in doing, for cases the nature of which could be exactly diagnosticated by the presence of a perceptible tumor, by decrease of strength and weight, scantiness of urine, etc. May be we shall even be told that ulceration and severe hemorrhages demand and permit surgical interference. Before that, however, there will be other indications. Loss of appetite may be benefited by bitters, nux, calumba, and, best of all, cundurango. Anæmia requires mild preparations of iron; constipation, a vegetable purgative, but no saline; pain, morphia internally or subcutaneously, but no chloral hydrate, which must be avoided in all conditions of irritability; eructation, charcoal or creosote; vomiting, morphia, creosote, hydrochloric acid.

Can we do more than simply treat the secondary symptoms? To a certain extent we can. A hundred cases of carcinoma which have come under my observation within these five years convince me of the efficiency of methylene blue. There are but very few patients but, if we commence giving small doses, say one to two grains daily, tolerate it well, and very few but are relieved and improved by it. I am not the only observer who has seen large tumors in any part of the body reduced in size by it, and smaller ones rendered almost imperceptible. If we cannot preserve life to threescore and ten, we can prolong it.

DISEASES AND DISORDERS OF THE STOMACH—MODERN SURGICAL TREATMENT.

By FREDERICK KAMMERER, M.D.,

NEW YORK.

But fifteen years ago surgical interference with the stomach was considered a most hazardous procedure, and was undertaken only in very exceptional instances. Since then, however, a great many indications have been found for operations on that organ, and it can only be regretted that the results of the latter have not, on the whole, been as encouraging as the indications have been many.

It seems natural that simple incision of the stomach for the removal of foreign bodies should have been the earliest of these. Quite a number of such cases are on record which have been done before the days of antiseptic surgery, with an astonishingly slight mortality. There is, therefore, no reason why the operation should not be practised to-day, when the shape and size of the foreign body are such that it cannot in all probability pass into the duodenum, and will cause irritation if it remains within the stomach itself. A clean incision, followed after extraction by a careful suture, ought to have practically no mortality.

The operation of incising the stomach, gastrotomy, has of late years been practised for other conditions than the one just mentioned. Several cases are on record in which the stomach has been opened for ulceration and consecutive hemorrhage, and I know of two cases in which this procedure has proved very successful. The one is reported by Küster—a woman, twenty-one years of age, who was very anæmic from repeated hemorrhages, and in whom the surgeon succeeded in effecting a cure by thorough cauterization of the ulcerated surface after incision of the stomach. The second is a case of Mikulicz, which to my knowledge has not as yet been published, also a young woman, in whom the bleeding point was found on the posterior wall of the stomach, the ulcer excised by cutting through the entire thickness of the stomach-wall, and the operation terminated by an exact suture at the point of excision from within and the line of incision from without. In this last case quite a large opening had to be made into the stomach to find the ulcer, increasing the risks of the operation. The patient, nevertheless, made an excellent recovery, to which I take pleasure in testifying, having examined her several weeks after operation. In a few other cases large ulcers have been excised with success, but not for hemorrhage. It should be stated, however, that death has also followed this measure of relief in several instances, and I fear that such will be the result in many more where grave operations are undertaken on exsanguinated patients. Gastrotomy for hemorrhage will always find a very limited application, for the reason that it will be difficult to determine the moment at which, without operative interference, a fatal termination would ensue.

Gastrotomy has been furthermore recommended by Loreta as a preliminary measure to divulsion in non-malignant stenosis of the pylorus, and has been employed in this way by many operators with good results. For this purpose an incision is made into the stomach nearer the pylorus than the cardia, and after introduction of both index-fingers into the pylorus, the latter is stretched with uniform but considerable force. The incisions in the stomach and the abdominal walls are then closed. The immediate result of this procedure has generally been excellent when the patient survives. The vomiting and gastric irritation have ceased and the patients have gained largely in weight, as a result of the unimpeded passage of food from the stomach. But certain accidents which have occurred during its performance, notably rupture of the pylorus with consecutive peritonitis and also hemorrhage, have caused it to be superseded by a plastic operation which has none of these disadvantages, but one further advantage, that it prevents a recurrence. It is not probable, judging from our experience with divulsion in other parts of the body, that a single stretching will be followed by a permanent disappearance of the contraction. And the ultimate results of Loreta's operation do not give support to such an assumption, Loreta himself having published three recurrences.

Pyloroplasty is based on an entirely different principle, that of leaving the stenosed portion of the pyloric ring intact and adding to its circumference by a very simple plastic operation. A longitudinal incision through the entire contracted portion of the pylorus is united in a transverse direction, as a result of which the line of suture now lies at right angles to the original incision into the pylorus, increasing by its entire length the circumference of the latter. This operation is the one which should be done by preference for the relief of non-malignant stenosis of the pylorus.

Very interesting comparative statistics have lately been published by Mintz on this subject. He has collected 22 cases of Loreta's operation, with 13 recoveries, *i.e.*, fifty-nine per cent.; whereas 29 cases of pyloroplasty, according to Heinicke-Mikulicz, are mentioned with 22 recoveries, *i.e.*, 82.7 per cent. If stenosis is complicated by ulceration, pyloroplasty is not indicated. We should then run the risks of a recurrence during further cicatrization of the ulcer. Gastro-enterostomy should be resorted to under these conditions, which, according to Mintz, gives a percentage of 71.9 of recoveries. Pylorectomy should never be done for non-malignant stricture.

For simple dilatation of the stomach, unaccompanied

by organic lesions at the pylorus, tucks have been made in a longitudinal and also transverse direction in the wall of the stomach, and fastened by sutures passing through the serous and muscular coats. The operation has been done with some benefit in consequence of the diminution in the capacity of the organ, but the same has generally not been permanent.

Very little encouragement can be gathered from the results of operative interference for perforating ulcers of the stomach. I have found only one case of recovery after this operation, and have myself lost a case some weeks ago, a man of about fifty, whom I saw on the fifth day with advanced general peritonitis. Although the patient gave a history of sudden acute pain in the epigastrium on lifting a heavy load, I was inclined, from his appearance, to diagnose an appendicitis, more especially as I could elicit only a very indefinite history of previous gastric disturbance. I made the usual incision at the outer border of the rectus, bringing to view a normal appendix. On continuing my incision upward the sudden appearance of undigested particles of food left no doubt as to the nature of the lesion. A perforation of about the size of a pea was found on the anterior wall of the stomach and closed with silk sutures. The entire abdominal cavity was irrigated with many gallons of hot sterilized water. The patient rallied somewhat, but died next morning. At the post-mortem examination a second perforation, much larger than the anterior one, was found on the posterior wall of the stomach.

The cases which most frequently come under the care of the surgeon are those of cancer, unfortunately only when unmistakable symptoms of pyloric stenosis have already developed, and when the tumor has already attained considerable size. Two operations have been adopted as justifiable ones for the relief of this affection: pylorectomy and gastro-enterostomy. Both of them have undergone many modifications since they were first presented to the profession. In pylorectomy, Billroth, whose experience has been larger than that of any other surgeon, always united the cut edges of the stomach and duodenum, after partially closing the opening in the former, with a view to making the two apertures of equal size. His mortality with this operation was very great, over fifty per cent., which he attributes mainly to faulty technique in suturing. Owing to the difficulty of uniting two intestinal openings of unequal size, it has been proposed, more especially by Bull in this country, to close the stomach and duodenum and to do a gastro-enterostomy. It has been further proposed to close the stomach and to implant the duodenum into a fresh incision on its anterior, or, preferably, its posterior wall, and not long ago the very ingenious device known as Murphy's button has been called into requisition to accomplish this object. There can be little doubt that the implantation of the duodenum into the posterior wall of the stomach is the most rational manner of re-establishing the continuity of the intestinal canal. If, however, owing to extended resection, an approximation is impossible, gastro-enterostomy should be resorted to, after closing the divided ends of the viscera.

When the surgeon, after opening the abdomen, finds the removal of the neoplasm inadvisable, what course should he pursue? If his patient is generally in a fair condition and symptoms of pyloric stenosis are well developed, then the case is one for some form of gastro-enterostomy. But I do not hesitate to say that the surgeon should again close the abdomen and desist from the temptation of further operative interference when the symptoms just mentioned are absent or present only in a slight degree. I believe that far advanced cases, where cachexia is well marked, do not stand gastro-enterostomy well. When the retro-peritoneal glands are involved, and also other abdominal organs, such as the colon and liver, it is better to run the chance of the stenosis not becoming apparent before the patient has lived through the short remainder of his life, than to subject him to an operation which in his condition is critical. When the stenosis has been well marked before laparotomy, however, there will be no alternative but to do gastro-enterostomy, although the prognosis is, if anything, worse. I have myself lost three cases on from the third to the fifth day, in which a most careful post-mortem examination has failed to detect the slightest sign of leakage along the line of suture, or any traces of peritoneal infection. In two of them persistent vomiting set in immediately upon their recovery from narcosis, and lasted, despite all our efforts, until death. (I should like to mention in this connection that Hahn has lately recommended washing of the stomach in such cases, as early as twelve hours after operation. He claims that this manipulation is without danger and that the vomiting will generally cease.) In the third, vomiting incident to narcosis ceased after a short time, but the patient died apparently of exhaustion. All these patients were very cachectic and anæmic, with well-marked stenosis. I cannot attribute their death to shock following operation, for they all rallied well from the effects of the latter, and were, in fact, in about a like condition at the close as at the beginning of the same. In two of them, some difficulty was experienced in bringing the loop of intestine to a suitable position on the anterior wall of the stomach, owing to cancerous infiltration of the latter, and some tension was present after completion of the anastomosis. This may have been sufficient, combined with the occasional discharge of bile and pancreatic juice into the stomach, to account for the persistent vomiting, which in patients of so low a grade of vitality may produce profound collapse and death. I do not, therefore, believe that cases of pronounced cachexia are favorable for this operation. Regarding the technique of the latter, I have but little to say. I have always attached the loop of jejunum to the anterior wall of the stomach, bringing it over the transverse colon, the original operation of Wölffler. Some surgeons have observed intestinal colic and obstinate constipation after this method, and attribute the same to pressure of the loop upon the colon. It has, therefore, been suggested to pass the loop through a slit in the mesocolon, behind the transverse colon, and to attach it to the posterior wall of the stomach. The latter procedure is more difficult and has not been generally accepted, although special conditions, as infiltration of the anterior wall of the stomach, may necessitate its employment. I have used Senn's plates, Abbe's rings, and the simple suture with silk, and prefer the latter. One of the first requisites of speedy union is uniform approximation of the peritoneal surfaces which are to become adherent, and to this object catgut rings, in my experience, do not so readily lend themselves. Senn's plates cannot be procured of sufficient size for a large opening between the two viscera, and such an opening is very essential to counteract the effect of contraction at the anastomosis. The best plan is, I believe, to make incisions, three or four inches long, and to suture, using a double row of peritoneal sutures on the posterior side, at least. I should not employ Murphy's button in gastro-enterostomy, as it has always seemed to me that it might ultimately slip into the wider cavity, the stomach, with the same facility as into the small intestine, and a report of three such occurrences at a recent meeting of the New York Surgical Society has corroborated this opinion. Moreover, I do not regard the matter of saving fifteen minutes' time as one of any importance in gastro-enterostomy, although in some forms of intestinal obstruction a loss of fifteen minutes may prove fatal.

Progress in the treatment of cancer of the stomach, will be made in the direction of pylorectomy. The conviction that early and very radical removal of cancerous tumors will vastly improve the results of operative interference, has been much strengthened lately

by the excellent work of Halsted on cancer of the breast. In the subject under discussion to-night the difficulty lies in early diagnosis. We have heard how these difficulties may to a large extent be overcome. But still, occasionally, a case may baffle the diagnostic skill of the most expert. All who have experience in this kind of work will agree with me, that careful examination, with or without narcosis, has often failed in detecting a tumor of considerable size, which laparotomy has readily revealed. If anywhere, an exploratory incision is certainly indicated here. Palpation of the upper abdomen does not yield results which are at all as reliable as those gained by simple or bimanual examination of the pelvis, where some have learned to feel even a normal appendix. If we, furthermore, remember that in about one-third of all the cases of cancer of the stomach, which have been examined post mortem, no metastatic deposits and no adhesions were found, we should expect to meet with very favorable conditions for pylorectomy, when early exploratory incision is practised. But popular prejudice, which, here as elsewhere, must be overcome to attain the most gratifying results, will only yield to the united efforts of both physician and surgeon.

THE USE OF VASO-CONSTRICTORS IN CARDIAC DISEASE.[1]

By REYNOLD W. WILCOX, M.D., LL.D.,

NEW YORK.

PROFESSOR OF CLINICAL MEDICINE AND THERAPEUTICS AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; VISITING PHYSICIAN TO ST. MARK'S HOSPITAL.

THE literature of the use of the vaso-dilators in cardiac disease is extensive; their exhibition is now widespread and productive of good results. Since the observations of Brunton in 1867 have been published, numerous clinicians have recorded the results of the administration of amyl nitrite, nitro-glycerin, and sodium nitrite, until to-day the use of the nitrites rests upon a secure foundation. The advantages of the use of the vaso-constrictors has not been so thoroughly before the profession. That they are useful, independent of any purpose of checking or of warding off hemorrhage, all admit.

That they are useful in a considerable proportion of cases of cardiac disease, I am, from eight years' clinical study of their effect, firmly convinced. The cases in which we may expect that they will demonstrate their greatest usefulness must be sharply defined. Evidently, in patients in whom the cardiac disease is secondary to diseases of the arteries, either endarteritis proliferans, periarteritis, calcareous degeneration of the intima, we will not find the vaso-constrictors indicated. This limitation also applies to Oertel's Terrain Kur, as has been well pointed out by Hayem. In an under-compensated heart, irrespective of whatever valvular lesion may exist, we can, by use of these remedies, exactly regulate the amount of work which the heart is made to perform. Obviously, by narrowing the calibre of the peripheral systemic arteries and the arterioles, we may increase the obstacle to the flow of blood and thus to a nicety regulate the work which the left ventricle is called upon to do. By thus regulating the work of the left ventricle we may set up hypertrophy of the muscular tissue in its walls, and in this way bring about compensation; not only does the increased blood-pressure result in more blood being sent into the coronary arteries, the nutrient arteries of the heart, but more efficient cardiac contractions produce a more rapid circulation of blood in the cardiac muscles, thus improving its nutrition. The same principle, that of regulating the work of the heart, is that involved in the Oertel cure of relatively weak hearts. We believe that the method of treatment by means of the vaso-constrictors to be the preferable one because it is absolutely under the control of the physician. Digitalis undoubtedly is the most generally useful of all of the drugs which are employed for the relief of cardiac disease, but only when it is properly used. Employed as it frequently is, without regard to the pathological circulatory conditions, it quite as often does injury to the patient as it affords relief. If one were asked in what circulatory condition digitalis finds its most useful indication, it can be safely said, as Fothergill long ago pointed out, that it is when the pulse is rapid, broad, and of low tension. It is here that passive congestions are most frequently found. It is in these cases that hemorrhages so often occur. Digitalis is useful because it is a vaso-constrictor of no mean value, and because in slowing the heart the organ acts at a better mechanical advantage, the diastolic period is longer, the heart-rest is increased in length, the systoles are more perfect. Clinically we see the anasarca diminish, the urine becomes more copious and of lower specific gravity as the renal congestion disappears, the cough, cyanosis, and dyspnœa are relieved as the pulmonary congestion diminishes, the dyspeptic symptoms are relieved as the portal system becomes unloaded of venous blood. The pulse-rate is slowed partly because of increased resistance, in the same way that a frog's muscle contracts more slowly as its load is increased, and partly because of the action of digitalis upon the cardiac peripheral end of the vagus. In this very vaso-constrictor action of digitalis we have a great source of danger—the danger of so increasing the work of the heart, so increasing the obstacle to outflow of blood from it—that the cardiac muscle will be unable to overcome the resistance and dilatation will supervene, and the slow pulse of full tension will become the rapid, and in the earlier stages of overdosing hard, in the later stages unfilled arteries. The disadvantages of digitalis, so far as its vaso-constrictor action is concerned, lie in the slow establishment of this condition, its persistent duration, and that it is not so amenable to the antagonists, the vaso-dilators.

Many years ago it occurred to me that if it were possible to separate the vaso-motor properties of drugs used for the treatment of cardiac diseases from their physiological action upon the pneumogastric, a decided gain for practical medication would be acquired. In selecting a remedy to control the calibre of the arteries considerable difficulty was encountered, for of the drugs which have vaso-constrictor properties, some, as for example, squill and convallaria when they have any effect, possess action similar to digitalis. Others, as belladonna, hyoscyamus, and stramonium stimulate the vaso-motor centre, their power being in the order named, but they also increase the heart's action. The influence of opium (small dose), of quinine, ether, and alcohol in this direction is hardly marked enough to warrant exclusive reliance upon these agents when used for the special purpose of vaso-constrictors. Nux vomica certainly stimulates the vaso-motor centre, but, as Delezenne has recently pointed out, it is undoubtedly an energetic dilator of the peripheral vascular plexus, although it has a vaso-constrictor effect upon the larger arterioles.

We are left, then, with five drugs from which we may choose our vaso-constrictor. Barium, lead, and silver are reported to be general vaso-constrictors; the first only has a decided action. Barium, especially the dioxide, acts as does ergot, directly upon the muscular tissue of the vessels, but its action is not so marked, is longer in duration, and is not so certain. Hydrastis is a vaso-constrictor of no mean value, but is chiefly useful in the congestions and hemorrhages of the uterus and adnexæ.[1]

To ergot, then, must we look for a general vaso-constrictor. The preponderance of the evidence obtained

[1] Read before the Section of General Medicine of the New York Academy of Medicine, December 18, 1894.

[1] See Wilcox, New York Medical Journal, 1887, vol. xlv, p. 199.

from experimental work is that ergot causes contraction of involuntary muscular fibre whenever found in the body; therefore we have constriction of the muscular walls of the arterioles. It also lowers the pulse-rate; this is partly due, as has been above stated, to the increased peripheral resistance. If administered hypodermatically its vaso-motor effects may be seen within a few minutes, these effects lasting for several hours, according to the activity and strength of the preparation and its method of administration. At all times the vaso-constriction is readily done away with by the administration of the vaso-dilators, the nitrites.

The mode of employment in the cases of cardiac disease marked by a pulse of low tension and passive congestion, has been to diminish the calibre of the arterioles by ergot, slowing the heart, if rapid, by strophanthus or sparteine, which have but slight action as vaso-constrictors, the last almost none at all. If the pulse is already slow the heart can be stimulated by caffeine, or preferably, by cactus, the last being inert unless made from the green plant. In these cases I have found, after years of clinical observation, that the process of bringing about compensation in relatively weak hearts was more easily accomplished and in shorter time, and by far more safely than by digitalis. About three years ago my attention was called to a series of papers by Hemmeter upon the physiological effects of ergot and its clinical applications, by far the most scholarly and practical study which I have ever read. In these papers was mentioned a liquid ergotin named by its manufacturers, Sharp & Dohme, "ergotole." It was stated that it was unchangeable, unirritating, so that it could be used hypodermatically, and that it was probably the most concentrated liquid preparation of ergot that can be obtained. In my clinical studies during the past three years I have made use of this preparation, and I can substantiate the statements made by Hemmeter. For other purposes for which ergot is employed but which do not come within the scope of this paper, I have found it equally useful. To keep the arterial tension so that the peripheral resistance shall be just within the power of the cardiac contractions, the dose must be proportioned to the strength of the heart. If the passive congestion (venous) is considerable, the renal congestion marked, dyspnœa, cyanosis, and pulmonary œdema urgent, five to twenty minims of "ergotole" hypodermatically, with one-half to two grains of sparteine sulphate, also hypodermatically, will often relieve as if by magic. If the case is one of under-compensation, the oral administration of from five to thirty minims in water, with which it makes a perfectly clear mixture, three times daily, will be required. For direct action upon the heart, strophanthus or sparteine, caffeine or cactus, will be needed, the dose to be carefully determined for each individual case. In this way I have succeeded in obtaining and maintaining compensation in a large number of cases of failing heart, in both hospital and private practice.

Conclusions.—1. For the relief of passive congestion and to establish compensation, the pulse being of low tension, the calibre of the blood-vessels should be contracted by vaso-constrictors, of which the most reliable is "ergotole." 2. For the regulating of the rate of cardiac contraction drugs which have little or no effect upon the size of the blood-vessels should be used—strophanthus or sparteine, caffeine or cactus.

The Strange Epidemic of Insanity which prompts its subjects to stab strangers, usually women, in the streets, has prevailed in London, and naturally makes ladies going about alone somewhat nervous.

A New Hæmostatic called ferripyrin has been discovered by a German apothecary, Wilkousky. It is an orange-colored powder composed of chloride of iron and antipyrin, slightly soluble in water.

Clinical Department.

A CASE OF ACUTE YELLOW ATROPHY OF THE LIVER.

By C. E. V. KENNON, M.D.,

PROVIDENCE, R. I.

On August 3, 1893, I was called to see a young woman, unmarried, aged twenty-nine, previously well, who had a marked jaundice of several days' duration. For over two weeks the case was treated as simple catarrhal jaundice. During this time the temperature was normal and pulse 72, not the slow pulse that is often found with jaundice. The urine was examined twice, and beyond the discoloration from bile showed a slight trace of albumin only. The area of hepatic dulness was enlarged, there was some headache, a good deal of lassitude, some vomiting, clay-colored dejections, etc., and, in short, the case went on like the ordinary catarrhal jaundice, up to August 19th.

On the morning of the 19th I was called out early to see the patient. She had suddenly developed violent cerebral symptoms — screaming, running about the house, and struggling when attempts were made to hold her on the bed, and then had gone into convulsions. When I arrived her convulsions and delirium were over, and she was lying quietly in bed. Her pulse was 130; temperature normal. She was rather dull in replying to questions, but gave rational answers. During the day convulsions and delirium alternated with partial coma. In the evening the pulse was 88; temperature normal.

The next morning, the 20th, the pulse was again 130; temperature, 99.5° F.; coma profound, continuing so from this time on, the violent cerebral symptoms having subsided completely. The mother told me that the patient had "come around," though she had been unwell only two or three weeks before. I found a dark, bloody discharge from the vagina, but not profuse.

After the onset of severe symptoms I told the mother that the girl could not recover, and at the request of the family asked Dr. Bowen to see the case. He suggested, though with little expectation of benefit, that strong cathartics be given, and good doses of jalap and cream of tartar were given, producing frequent watery evacuations, without other result. At 11 P.M. the pulse was 150; temperature, 101° F.; respiration harsh and rapid. Dark bloody mucus and saliva were dribbling from the open mouth. The jaundice was intense. The lower border of hepatic dulness was a couple of finger-breadths higher than at the last previous examination (several days before). Whether this was due to displacement of the colon or actual shrinkage of the liver, I cannot say. The whole area of dulness was now about normal. I could make out no increase of splenic dulness.

On the morning of the 21st the pulse was 154; temperature, 99.5° F.; respiration, 32, loud and harsh; and a dark bloody ooze from mouth and genitals. Death occurred at about 11 A.M., a little over two days after the "explosion," or second stage, began.

The history of this case, the first stage exactly like simple jaundice, the sudden onset of the second stage, the cerebral symptoms, behavior of the pulse, temperature, respiration, hemorrhages, etc., and rapidly fatal termination, age and sex of patient, all correspond to the clinical history of acute yellow atrophy of the liver, as described in the text-books. Although it is quite rare, the symptoms characteristic were so marked that such seems the only logical diagnosis. No urine was obtained in the second stage, so no examination was made for leucine and tyrosine, nor for the amount of urea present, and in the first stage they were not thought of. There is the so-called "pernicious jaun-

dice," with symptoms very similar; but that occurs, as a rule, after long-continued jaundice, where it is secondary to some chronic obstruction, as cancer, gall-stone, or some hepatic disease.

There was no autopsy to confirm the diagnosis. The undertaker was ready with a diagnosis of his own, and acted promptly. He told the family that the disease was yellow fever, and the body must be buried as soon as possible. My assurance that there was no danger could not overcome the scare of the relatives, and the body was buried, I believe, in less than twenty-four hours after death, and it was then too late for an autopsy.

October 31, 1894.

ACUTE GONORRHŒAL VULVO-VAGINITIS AND URETHRITIS IN AN INFANT AT BIRTH.

BY JULIUS MORGENSTERN, A.B., M.D.,

NEW YORK CITY.

CLINICAL ASSISTANT IN CLINIC FOR CHILDREN'S DISEASES AT POST-GRADUATE HOSPITAL; LATE RESIDENT PHYSICIAN TO ST. MARK'S HOSPITAL.

This case is reported because it is not often that we can so distinctly demonstrate by the etiology the physical and subjective symptoms, and by microscopic aid the presence of a gonorrhœic process in an infant from the time of its birth.

This little patient was first seen on October 15, 1894, in Dr. L. Fischer's Clinic for Children's Diseases, at the Post-Graduate Hospital. There was a history of a scant passage of urine since its birth, which event took place three weeks previously; the little urine that was passed was discharged guttatim. On local examination of the genitals, nothing could be seen except possibly a slight reddening; there was no sign of any local discharge. A probe introduced into the urethra encountered no obstruction. On percussing the bladder no fulness could be detected. The child seemed bright enough, and its face depicted no sign of pain. No positive diagnosis was possible.

The babe was again seen on October 22d. On local examination quite a different picture was presented. The mucous membranes of the labia majora, nymphæ, vestibule, and anterior portion of the hymen were reddened and engorged, and so tender and painful that the child screamed when the parts were touched; there was a thick, creamy, muco-purulent discharge present; there were excoriations about the perineum. More urine was now voided than formerly, but the quantity was still very small.

Upon questioning the mother, she admitted that she had been under treatment for a long time for a vaginal discharge similar to that from which the child was now suffering. As the child slept with the mother, this showed positively that there was a direct transmission of the gonorrhœa from mother to child, a history of as direct an infection as could ever be obtained.

These local and general symptoms with the etiology gave conclusive evidence of what we had to deal with, and there was only need of the supplementary aid of the microscopic examination of a little of the discharge, to demonstrate the presence of the gonococci. For microscopic examination a little of the discharge was dried on a cover-glass, and stained with methylene-blue. The gonococci were found in large numbers, both separately and in the pus-cells themselves. The microscopic specimen was examined by all the doctors in the Children's Class of the Post-Graduate Hospital, and all commented upon the clearness with which the gonococci were seen, and also upon their great number.

The treatment consisted in rest to the parts, cleanliness, antisepsis, and the use of an astringent—briefly, in local bathing and syringing with a warm sublimate solution (1 to 10,000); Beta naphthol bismuth powder was well dusted upon the inflamed parts; then boracic acid lint was placed between the vulva to absorb the discharge; the diaper answered the good purpose of an occlusion bandage. No other treatment was necessary.

Under this treatment improvement set in rapidly, and within a short time the child was entirely well.

A CASE OF TONSILLITIS, WITH ERYTHEMA.

BY ROBERT BOYD, M.D.,

ASSISTANT SURGEON, U. S. NAVY.

On March 13, 1894, Alfred E——, twenty-four years of age, occupation sailor, reported at sick-call, complaining of a "sore throat," which he had first noticed when he got up in the morning.

On examination of his throat, his tonsils were found to be very much enlarged and congested, touching each other and to a great extent filling up the fauces. Their surfaces were covered with a grumous, tenacious mucus, and the follicles were prominent and unhealthy-looking. The patient also complained of difficult and painful deglutition. Temperature, A.M., 101.2° F.; pulse, 108; respiration, 20. Bowels constipated and tongue heavily coated.

The patient was admitted to the sick list and placed upon phenacetin, grains 15, and quinine, grains 10, *t.i.d.* An antiseptic spray was directed to the parts three times daily. Fluid diet, mostly consisting of milk and beef-tea.

Examination of the urine showed a small amount of albumin, which can be accounted for by the fever; it is scanty and high colored. Reaction acid and no casts. Treatment was continued and flaxseed poultices applied to neck during the day. Pulv. ipecacuanhæ et opii, grains 10 at night.

On March 15th, an erythematous eruption developed on the arms, legs, and back, very much resembling the eruption of scarlet fever. On questioning the patient, he stated that a week ago he had held a sick child in his arms, at a friend's house. The mother told him that the child had "measles." As will be seen, the eruption appeared seven days after a possible exposure, and the usual period of incubation of scarlet fever is stated to be about seven days. We can only take the mother's statement that the child had "measles," or some erythematous disease, for what it is worth.

The throat being somewhat characteristic, and the presence of the eruption in connection with the history of the case, I strongly suspected scarlatina. The tonsils at this time, having somewhat softened, I incised them, with strict attention to asepsis, evacuated considerable pus, and painted the surfaces with a three per cent. solution of carbolic acid.

Patient slept well during the night and was much improved the next day. Tonsils looked healthier, were less congested, and there was but slight pain in the throat. The erythema persisted. Temperature, A.M., 101°; P.M., 102° F.; pulse, 100. Antipyretics were discontinued, in order to determine whether or not they have caused the erythema.

On the following day the patient was much improved. Temperature, A.M., 101.4°; P.M., 102.2° F.; pulse, 106. The erythema had extended to the hands and feet. The patient complained of pain in the wrists and in the finger-joints. There was slight swelling of these parts. There was no history of any attacks of rheumatism. There was a steady improvement up to the 21st of March, 1894, when the temperature and pulse became normal.

On March 24, 1894, the patient's term of enlistment in the naval service having expired, he was discharged from the sick list, at his own request, apparently cured. The erythema was still present, but less intense.

The patient was not seen again for a period of three

weeks, when he returned to re-enlist. At this time he was feeling strong and well. The erythema had entirely disappeared.

United States Naval Hospital, Philadelphia, Pa.

"DIRECT TRITURATION" IN RIPENING IMMATURE CATARACTS.

By W. C. PIPINO, M.D.,

des moines, ia.

In view of the fact that some of our high authorities have expressed themselves unfavorably in regard to ripening immature cataracts, regarding the process as dangerous and not to be performed, I feel that any additional experience in this field, though it emanates from a source not so distinguished, is worthy of attention and consideration.

The method most frequently mentioned in the textbooks for artificially ripening cataracts is Förster's. The chief objection to it is the mutilation of the iris by an iridectomy and possible injury to the cornea from attrition. By direct trituration, the method devised and introduced by Boern Bettman, these objections are overcome, and when performed by skilful hands the method is the acme of perfection. The careful reading of Dr. Bettman's paper on "Ripening of Immature Cataracts by Direct Trituration" impressed me favorably, and I determined to give it a trial when an opportunity presented.

I have now performed the operation seven times, and in no instance have I had occasion to regret it. I am confident that each individual whose lens I have thus ripened would be still groping around in semi-darkness, had I refrained from interfering with the slow process of nature, and instead, given the advice I have in the past, to "wait until the cataracts are ripe before an operation can be done."

Noyes tells us "the process of sclerosis goes on for ten or more years." This is true, and it is in this class of cases that the operation is designed to hasten maturation and restore to the individual useful vision by an early operation.

One of the chief objections urged against direct trituration is rupture of the suspensory ligament and dislocation of the lens. Dr. Bettman, in his paper published in the *Journal of the American Medical Association*, November 4, 1893, in reply to this criticism says: "I can only reiterate that careful and skilful manipulation of the spatula in my hands has never been followed by any untoward symptoms; seemingly the most probable misadventure would be tearing of the suspensory ligament and dislocation of the lens."

The first time I performed the operation I succeeded in doing the worst thing that could possibly happen —I ruptured the suspensory ligament. However, this did not prevent a good recovery with useful vision by a subsequent operation. This accident, occasioned by my awkwardness, did not deter me from resorting to the method in other cases. I discovered by this experience that the amount of pressure to be used in triturating a lens is to be acquired by experience only. I exerted too much pressure on the lens, which I avoided in my other cases. I now employ just sufficient pressure to break down the lens structure. It is surprising what little pressure will cause an immature lens to become wholly opaque. In twenty-four hours you can see the change, and in the majority of cases it is opaque at the end of the first week. The cases in which I triturated the lenses, the individuals could see barely enough to get around and avoid coming in contact with objects, and not sufficient vision to follow any employment, read, or sew. One case of an old gentleman, in particular, who had been groping his way about for several years, was told by several professional gentlemen whom he consulted before coming to me, that he must wait, as nothing could be done until his cataracts were ripe. In each eye there was a small opaque nucleus around which the fundus could plainly be seen.

The operation of ripening the lens artificially being fully explained to him, he readily submitted, and in four weeks from the date of trituration simple extracting was performed, followed by good vision. My experience is limited to five cases and seven eyes. Some of the patients being so well satisfied with one eye, they refused to submit to an operation on the other. In no instance did iritis occur. This was guarded against by the instillation of atropine. In one case I extracted the lens too soon after trituration, and I was compelled to wash out the anterior chamber to free it of cortical matter before I could get a clear pupil. I wait now from four to five weeks before attempting extraction. In the light of my present experience I do not hesitate to urge the operation in suitable cases, as I believe it is free from danger and enables us to restore patients to a life of usefulness and pleasure when they would otherwise be compelled to wait many weary months under the old plan.

RHINOPLASTY.[1]

By EARL M. GILLIAM, M.D.,

columbus, o.

Mrs. G——, aged forty-five, nervous temperament, subject to extreme attacks of neuralgia, consulted me about two years ago, in regard to a growth near the inner canthus on the left side of the nose. This appeared eight years previous. Having diagnosed it as morphea, but not being absolutely sure, I advised her to consult some good skin specialist. She consulted Professor George Henry Fox, of New York City, who pronounced it to be morphea, while Professor Piffard called it epithelioma. Dr. B. Merrill Ricketts, of Cincinnati, termed it morphea and operated on her December, 1892, removing the left eyeball and the left side of the nose, together with the entire lower and part of the upper eyelids.

At the expiration of six weeks' treatment, she returned home and placed herself under my care. Owing to the loss of the periosteal coverings of the nasal, lachrymal, and nasal process of the superior maxillary bones, they became necrosed, and I removed them at different periods. They left a very ugly-looking hole, and on December 11, 1893, I concluded to try and restore the entire left side of the nose by a rhinoplastic operation.

On account of the vast amount of cicatricial tissue ensconcing the opening, I was exceedingly apprehensive of the ultimate result. Having disinfected the parts, a piece of oiled silk one-third larger than was needed to cover the parts to be restored, was placed upon the forehead in such a manner as would give an angle to the flap, which when twisted upon itself could not interfere with the circulation of the pedicle. Commencing at the inner canthus of the right eye, an incision was made down to the periosteum, and following the outline of the pattern, ended at the top of the bridge of the nose. The angular artery (which by the way is a most important factor as regards the ultimate result, was included in the flap, as it furnishes nutriment to its tissues. The flap being dissected back, was placed upon absorbent cotton impregnated with bichloride of mercury, and the cicatricial tissue at the edge of the opening removed. Having arrested the hemorrhage, the margins of the flap were dove-tailed into the edge of the opening by numerous silk sutures one-eighth of an inch apart. The gap on the forehead was closed by dissecting back the tissues a sufficient distance, so as to allow coaptation by hare-lip pins, with figure-of-eight sutures. Warm-water dressings being applied, all things progressed favorably until the ninth day, when suppuration set in, and threatened to destroy the entire flap. This was finally arrested; but an open-

[1] Read before the Columbus Academy of Medicine, October 3, 1894.

ing one-fourth by one-fifth of an inch, on bridge of nose near the tip, was left unhealed. From this time the flap gradually became hypertrophied, and bulged out quite conspicuously, the edges being inverted.

February, 1894, I undertook to close the opening by paring and bringing together the edges with silk sutures, but this failed to materialize.

April 14th.—It was decided to remove the prominence produced by the twisting of the pedicle. Under ether, an elliptical incision was made over same, and all redundant tissue removed; the edges approximated by silk. On the fourth day the sutures were removed and the parts found nicely coaptated.

September 20th.—Another effort was made to close the fistulous opening on the bridge of the nose. This was done at St. Anthony's Hospital. Etherizing the patient, the edges of the opening were pared and all cicatricial tissue removed; the parts were then brought together with silk sutures.

Other incisions in the form of an ellipse were made near lower part of flap, and all of the remaining redundant tissue removed.

During this operation the hemorrhage was terrific and nothing could control it, except long continuous pressure by sponges dipped in boiling water. At the expiration of the third day the sutures were removed, and on the fourteenth day I found the edges entirely healed, except a pin-hole fistula which at this time still exists.

On inquiry I find that this is the second, if not the first, operation of its kind that has been performed in Central Ohio. Our late and most honored colleague, Dr. David Halderman, intended to perform an operation of this character, but as yet I have no authenticity of such. In presenting this case I doubt whether those operators who have performed rhinoplastic operations encountered more difficulties or complications than existed in the above case. They were as follows:

1. An extremely neurotic patient, verging on insanity, produced by a constant dread that the disease was of a malignant type. 2. Having been for years a subject of excruciating attacks of neuralgia, she became emaciated and despondent. 3. Owing to the loss of the lachrymal canal the secretions from the socket constantly bathed the cheek and surrounding structures, excoriating the parts and delaying healing between the edges of the flap and cheek. 4. The reparative power of the tissues was exceedingly limited.

Since the above was written, I succeeded in closing the fistula, after having many remedies prove fruitless, by applying a fifteen per cent. solution of ichthyol in olive oil two or three times daily.

50 North Fourth Street.

Progress of Medical Science.

The Treatment of Apoplexy—Dr. Preston, of Baltimore, believes that in the treatment of apoplexy more might be done in the prodromal stage if this condition were more carefully studied and oftener recognized (*Maryland Medical Journal*). There are no constant or certain prodromata, but in a considerable proportion of the cases here related the history obtained afterward from the patients showed the existence of headache, vertigo, or a sense of fulness in the head, numbness of one side, etc. These symptoms in some instances existed for a week before the apoplectic attack. It is very important to heed these warnings, especially in cases where there is atheroma of the vessels, or where there is high arterial tension without atheroma. Rest, vascular sedatives, nitro-glycerine, large enemata, will often modify the force of the circulation and thus tend to avert the rupture of the artery. Some years ago the writer called to see an elderly woman, stout, with flushed face, headache, and unusually high arterial tension. While waiting for the family physician she was kept absolutely quiet with ice to her head. While consulting in the next room the patient, against orders, got up to use the commode; the arteries could stand no further strain, rupture occurred, and she died in half an hour with all the symptoms of intra-cranial hemorrhage. Venesection would probably have averted this disaster. It rarely happens that the physician sees clearly enough to make use of bloodletting. After the rupture of the artery has taken place, it is doubtful whether venesection does any good. The most important part of the treatment of apoplexy is rest. There is no way by which the bleeding can be stopped, and it is probable that in the great majority of cases the increased intra-cranial pressure tends to control the hemorrhage. The ruptured artery or miliary aneurism is small, as a rule, and it is generally soon occluded by clot. If the amount of hemorrhage is moderate and not in a vital part of the brain, recovery, more or less complete, will take place if the clot remain in its first position. Very often it happens that the original location of the clot was not specially dangerous, but from gravity, or as the result of exertion, the clot has forced its way through the soft brain-tissue and done irreparable injury to more important structures. This can often be seen post mortem, and the track of the clot made out. From this it follows that the greatest care should be exercised to prevent any more moving of the patient than is absolutely necessary. If it be possible, the patient should be laid down on a sofa or mattress in the room where the attack occurs, and no attempt at movement made for twelve or twenty-four hours. It is better to slightly elevate the head by pillows, since this probably tends to modify the force of the heart's action in the cerebral vessels, and at the same time allows respiration to be carried on rather better than when the patient is perfectly flat. Opening the skull has been resorted to, but it is doubtful whether this is advisable, except in the case of meningeal or cortical hemorrhage. The ice-cap to the head is of some use in allaying restlessness, and is extremely good treatment for the relatives and friends. In regard to drugs in this early stage, there are practically no therapeutic indications that can be successfully met. The use of ergot and that class of remedies is of more than doubtful propriety. Aconite may sometimes be used to advantage in controlling a too forcible heart's action. As soon as the patient can swallow, it is the author's custom to administer a mixture of bromide and iodide of potassium, 30 to 40 grains of the former and 10 grains of the latter, and this is kept up for several days, then the bromide is omitted and the iodide used alone in increasing doses. In regard to the custom of administering croton oil or some drastic purge during the early stage, although sanctioned by almost immemorial usage, it is not only useless, but exposes the patient to the risk of making dangerous exertions, besides putting him in a filthy condition. The same objections in part apply to blistering and to the use of mustard. It is important to attend to the bladder and draw off the urine at regular intervals. The throat should be kept as free from mucus as possible and the surroundings of the patient rendered comfortable. These points have perhaps been dwelt upon with unnecessary minuteness, but one so often sees these cases handled in a mischievous manner. The physician, realizing the futility of any active treatment, is too apt to yield to any suggestion made by the family, and the object of this paper is to insist upon a simple and rational treatment of this condition.

The Opium Commission which was sitting last winter in India cost the Government $100,000, half of which expense fell upon the British, and half upon the Indian exchequer.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, February 2, 1895.

THE WEIGHT OF THE HUMAN BODY.

A SECOND Sanctorius has appeared in the person of Dr. De Parville, a French physician, who records his experiences in *Le Correspondant*. Dr. De Parville thinks we are all wrong in our ideas and methods of weighing the human body. He says: "I have weighed myself regularly every day, at the same hour in the morning and under identical conditions, and to-day I possess a record of five years of experiments conducted with the utmost precision. Every day when weighing myself I record the barometric and hygrometric variations, the temperature, and the dinner menu for the day. These experiments have convinced me more than ever that our weight is in a perpetual state of fluctuation. After eliminating the errors of the instrument, our weight varies, subject to innumerable influences. After breakfast, on a warm day, one loses more than one hundred and fifty grammes an hour."

Dr. De Parville describes in detail the various modifications in human weight, and naturally concludes that an exact knowledge of its fluctuations is very important.

The scales he says are not without their importance in medical practice, especially with infants. The weight of an infant increases in definite proportion during the first weeks of life, and there can be no departure from this regularity of increase without impairment of health. For adult persons, too, it is good to consult the scales, for they are the barometer of health. Any sudden increase of weight, amounting to a pound or so in a day, indicates a tendency to disease. It is evidence of health when the weight does not fluctuate more than three or four ounces from day to day. Great fluctuation implies functional derangement.

Dr. De Parville might have added a good deal to the value of his communication if he had given some of the fundamental facts regarding human weight which anthropologists have collected. The average weight of man, based on statistics collected by Quetelet, Krause, Beneke, Busch, and Hoffmann is 65 kilogrammes, or about one hundred and thirty pounds; that of woman is 55 kilogrammes, or 110 pounds. The variations of normal weight given by Quetelet are 120 to 140 pounds (for the French). Very few people know how much their clothes weigh, but anthropologists have made it a matter of serious study, and Quetelet estimates them to average one-eighteenth of a man's weight and one-twenty-fourth of a woman's. This latter figure must certainly be too low for the prevailing modes. Assuming the estimate to be correct, however, a man's clothes weigh about seven and one-half pounds, and a woman's 5 pounds.

The different parts of the body have been weighed by Harless, and form a contribution to his work on plastic anatomy. The head weighs about nine pounds (4.56 kilogrammes); the hand weighs about a pound, and the foot a pound and a quarter.

These are only a few of the facts of organosthamology with which we regret that Dr. De Parville did not enrich his paper.

THE MISSING LINK FOUND AT LAST.

DR. D. G. BRINTON writes to *Science* under this title and says that Dr. Eugene Dubois, a Dutch army surgeon stationed in Batavia, Java, has found the "link." He, the surgeon, describes three fragments of three skeletons which have been exhumed from the early pleistocene strata of Java, and which introduce to us a new species, as well as a new genus and a new family, of the order of primates, placed between the *Simiidæ* and *Hominidæ*.

The material, we are told, is sufficient for a close osteological comparison. The cubical capacity of the skull is about two-thirds that of the human average. It is distinctly dolichocepalic, about seventy degrees, and its *norma verticalis* astonishingly like that of the famous Neanderthal skull. The dental apparatus is still of the simian type, but less markedly so than in other apes. The femora are singularly human. They prove beyond doubt, says Dr. Brinton, that this creature walked constantly on two legs, and when erect was quite equal in height to the average human male. Of the various differences which separate it from the highest apes and the lowest men, it may be said that they bring it closer to the latter than to the former.

The line of descent, according to Dr. Dubois is: *Prothylobates*, *Anthropopithecus sivalensis*, *Pithecanthropus erectus*, *Homo sapiens*.

The discovery of Dr. Dubois leads him to think that man originated on the southern slopes of the Himalayan chain, which is, after all, not so far from the Garden of Eden; and is just south of the present abode of the mystical Mahatmas. We trust that Dr. Dubois is *homo sapiens*.

THE APOTHEOSIS OF CHRISTIAN SCIENCE.

ON the first Sunday in the year there was dedicated, in Boston, a meeting-house known as the "Mother Church" of the Christian Scientists. It is on the corner of Norway and Falmouth Streets, has an auditorium that will seat thirteen hundred people, and is said to have cost $200,000.

We have no special complaint to make of the criticism of Christian Science which Mr. E. S. Martin makes in *Harper's Weekly*. It is liberal yet critical, conciliatory yet approximately damning. Like most criticisms upon fantastic social phenomena we are told that there is much good indirectly and educationally to be derived from it. In particular do social students

impress their readers with the fact that doctors will learn much from "Christian Science" and allied forms of therapeusis. "The inventor of Christian Science," says Mr. Martin, "was Mrs. Mary Baker Eddy, a seeress who lives in Concord, N. H., and whose countenance, as her pictures represent it, bears an amusing likeness to that of that other familiar benefactor, the late Lydia E. Pinkham. Mrs. Eddy's written works seem to the ordinary comprehension to be exceedingly bad reading. Laurence Oliphant's religious writings are not much worse, and that is putting the case strongly. But as there was a great deal more sense in Oliphant than anyone who had read only his 'Scientific Religion' could have believed, so there must be more sense in Mrs. Eddy than any uninspired understanding can win out of her books. The sect that she started has certainly thrived. It is true that nine-tenths, or perhaps even a larger proportion, of its adherents have been women, but many of them are able to maintain a successful appearance of being extra-clever women. Sickness has undoubtedly been cured, and is constantly being cured in the name of Christian Science. That proves nothing by itself, but the history of Christian Science 'cases' is often interesting, and appearances often indicate the use of a definite therapeutic force which ordinary physicians neither attempt nor assume to exercise.

"More impressive than even the Christian Science cures is the complete satisfaction of the 'scientists' with their persuasion. It seems to become their first interest in life, as perhaps must be the case with any form of religion which really takes hold of the believer. It makes them happy, too, as any controlling enthusiasm does while it lasts, and Christian Science in many cases seems to last very well. But it is hard in this world to get anything for nothing. No one gets much out of Christian Science who does not put a good deal into it. Whether the gain is worth the investment is a question. It seems to be worth it to some people, but they are usually people who have turned to it as a desperate alternative, and stuck to it because it seemed to help them when nothing else did. To people who are not in desperate extremity, the disadvantages of Christian Science usually seem to outweigh its allurements.

"Whether Christian Science will last and continue to grow is a question about which there are many opinions. The present paragrapher guesses that it will fade out after a while, but not soon, and not without exerting some influence both on theology and medicine. It scandalizes the doctors on one side and the reverend clergy on the other, and it has fun with both. They will probably beat it in the end, but they will both be the wiser for meeting it."

The thing that seriously presents itself to physicians, however, is the enormous amount of harm directly and indirectly done by such institutions. He sees the cases of neglected disease, ruined health, and demoralized households, reports of which are never published. We do not say that there is no good in it, but that it remains to be shown that the good outdoes the harm.

The American Neurological Association will hold its next annual meeting at Boston, on June 5, 6, 7, 1895.

THE MILITIA MEDICAL STAFF.

The laudably prompt manner in which the order was obeyed for the First Brigade of militia to protect Brooklyn in the recent strike riot, brought with it only a minimum amount of difficulty in attending to the immediate requirements for the well-being of the command. Within an incredibly short space of time the entire brigade was, through its ordinance, commissary, and medical departments, fitted for field duty. It is with no small show of pride that we refer to the admirable arrangements made by the surgeons of the different regiments to meet any urgent requirements in their departments. Officered by thoroughly competent surgeons, who are specially trained for camp and field duty, with some of our brightest medical men in the ranks willing and able for special details, and with well-equipped and well-disciplined ambulance corps, our militia soldiery need to be congratulated on the incomparable excellence of this arm of the service.

Happily no serious injuries were inflicted upon the soldiers, although the cowardly attacks of the mob from the streets and housetops exposed the guards and pickets to even greater danger than in line of battle. The inclement weather, and the necessarily prolonged guard duty resulted in considerable sickness among the different commands on duty, but the prompt and efficient watchfulness of the regimental surgeons averted what would otherwise have been an ominously large sick list. The citizens of New York glory in their well-disciplined and ever-ready militia, and the profession is equally proud of the medical staff, so well represented in the different regiments.

THE CATHOLIC CHURCH AND OBSTETRICAL SCIENCE.

The Bishop of Augsburg recently issued a pastoral on the subject of obstetric practice in which he took the stand, upon which all Catholics are usually supposed to be agreed, that the induction of artificial labor, the child being yet alive, is under no circumstances allowable. It is, in the words of the pastoral, "a sin and morally reprehensible" for a physician to induce artificial abortion, no matter how imperatively the safety of the mother demands it. That this, however, is not the authoritative teaching of Rome is apparently shown by an anonymous writer (whom, however, the editor endorses as "inspired") in the *Munchener medicinische Wochenschrift* of December 25, 1894. The writer says that the Bishop of Augsburg speaks without proper authority, and that his injunctions are binding at the most upon the faithful in his own diocese, and must not be accepted as the universal teaching of the Church. The Catholic Church, he says, whatever overzealous and uninstructed individual members of it may do or say, is never inimical to true science. In support of this writer's contention that premature delivery, when absolutely necessary to save the life of the mother, is not contrary to the teachings of the Church, he quotes Dr. Wirthmüller, Professor of Moral Theology at the University of Munich, and Father Lehmkuhl, a well-known Jesuit theologian. The former authority

says that a sacrifice of the fœtus can never be permitted except when the mother's life is so jeopardized by pathological changes induced by the pregnancy, that the only possible means of saving her is to terminate the latter artificially. Lehmkuhl, speaking of craniotomy, says that there are not wanting writers who defend it when the life of the mother is in great danger. He himself is more cautious, yet says that he would leave the one performing such an operation in good faith to be judged by his own conscience, provided only that he had baptized the infant before perforating. Finally the writer recalls a judgment which was formally expressed by a congregation of cardinals in Rome. The question was submitted whether craniotomy, or any operation directly tending to destroy the life of the fœtus in utero, was ever justifiable. The sacred congregation replied that, "after mature deliberation, it would advise the questioner to follow the most approved authorities, whether ancient or modern, and act prudently." In other words, Rome would not condemn the operation if performed under the authority of approved medical teaching, and in the interests of the mother. This is certainly a logical as well as conservative opinion, for if it is wrong to take one life to save another, it cannot be lawful to suffer two lives to be destroyed when one might have been saved.

SULPHUR AS A SUBSTITUTE FOR IODOFORM.

At a recent meeting of the Royal Medico-Chirurgical Society, Mr. Arbuthnot Lane read a paper on the employment of sulphur as a germicide dressing. He took the dressing up as a non-poisonous substitute for iodoform, from the effects of which he lost a patient last year. He began to use it about a year ago in disease of the hip-joint, and naturally found that it produced a sharp caustic effect on the tissues, with escape of sulphuretted hydrogen. He reported cases of extensive tubercular disease of elbow, knee, tarsus, prostate, and spine, of septic gangrene of the leg, of lupus, and of carbuncle. He found he could sterilize healthy tissues, so far as organisms are concerned, by applying the powder for twenty-four hours, but in granulating parts, or such as were badly supplied with blood, as, *e.g.*, the brawny edge of carbuncles or spreading gangrene, a much longer time was required. No doubt the sulphur is slowly oxidized and sulphurous acid is the real disinfecting agent. Some of this is further oxidized, and the sulphuric acid which results is responsible for the caustic action observed. Still, as Mr. Lane found the dressing painless, the caustic acid must be formed very slowly and to only a slight extent. It was suggested that sulphurous acid might as well be used directly, as it was at Metz during the Franco-Prussian War in 1870, with very great success. But even long before that time it was loudly applauded as the great sulphur cure for diphtheria, foul abscesses, and other conditions where its disinfecting power could be utilized in liquid and in sprays. The powder has also enjoyed considerable repute in diphtheria and other diseases. There are, no doubt, cases in which the sulphur in powder is not only the most convenient form, but in which the gradual evolvement of the gas may be the most effectual. Mr. Lane may, therefore, be commended for reinforcing the use of one of the most ancient remedies, though all he stated could have been forestalled by therapeutists who know the history of remedies.

News of the Week.

The Medical Society of the State of New York will hold its eighty-ninth annual meeting in Albany, on Tuesday, Wednesday, and Thursday, February 5th, 6th, 7th, under the presidency of Dr. George Henry Fox, of New York City.

Municipal Health Changes.—A bill has been presented to the State Senate of New York, to provide for a physician as president of the Health Board, and also one to separate the Department of Charities from that of Correction.

Bequests of the Late Dr. Alfred L. Loomis.—The estate of the late Dr. Loomis amounted to $1,000,000. By his will a fund of $25,000 is created for the Loomis Laboratory, the income to be applied annually to its use. To the New York Academy of Medicine is given $10,000, to be known as the "Loomis Entertainment Fund," the income to be used annually in providing entertainment for the fellows of the college.

Dr. Joseph Fanyou, a prominent physician, who had been practising in New York City for about twenty years, but who had a residence in Bridgeport, Conn., died at his home in that city, January 25th, aged fifty-four.

Recent Returns have been made in Paris as to the application of the antitoxin treatment. In 2,700 cases of diphtheria previous to January 1st, there were 433 deaths, or sixteen per cent. This reduction in the mortality is about one-half.

The Berlin Debate on the Diphtheria Antitoxin.—To sum up the whole debate, the feeling generally was that the time has not yet come to pronounce a final judgment on this important question, as it could not be clearly proved that the lowering of mortality was due to the treatment or to the milder character of this year's cases. But all were agreed that the complications reported by Dr. Hansemann as following upon the treatment were of no importance, and that no patient had come to any harm by the injections. It was a subject of general remark that none of Professor Koch's or Professor Behring's assistants said a word in the debate.—*Lancet.*

A Proposed Hospital for the Homœopathic Insane.—A bill has been introduced in the Illinois Legislature providing for the establishment of a hospital for the insane, to be managed on "homœopathic" principles, whatever they are. The existence of the "homœopathic" sect shows some mental aberration, but this is the first public admission we have seen that any considerable proportion of them required confinement. There is nothing infinitesimal about the proposed appropriation, as the bill provides for an expenditure of $400,000.

The Cleveland Medical Society held its annual meeting on Friday evening, the 11th ult. Officers for the ensuing year were elected as follows: *President*, Dr. William E. Weir; *Vice-Presidents*, Dr. A. F. House and Dr. Henry S. Upson; *Recording Secretary*, Dr. W. F. Brokaw; *Corresponding Secretary*, Dr. Frank S. Clark; *Treasurer*, Dr. N. Stone Scott. In the address by the retiring president, Dr. W. H. Humiston, it was stated that the society had 291 members, and that the average attendance at the meetings during the year had been 135, so that in the matter of attendance it was second to no medical society in the United States. The meetings are held once in two weeks.

The Late Dr. James Hewitt.—At the regular meeting of the New York Otological Society, held at the Academy of Medicine, January 22, 1895, the following resolutions were unanimously adopted and incorporated in the minutes of the Society. "The New York Otological Society desires to place upon its minutes the sense of the loss it has sustained in the death of Dr. James Hewitt, one of its founders. Although but a young man at the time of his death, Dr. Hewitt had already attained a prominent position in his profession, and had he lived, would undoubtedly have become one of the distinguished aurists of his time. With a singularly retiring and quiet nature, he had a most genial and cheerful disposition, and a simplicity of bearing, and kindliness in speech and manners, that endeared him alike to his friends as well as his patients.

Resolved, That these resolutions be printed in the medical journals of this city, and that a copy of the same be sent to the family of the deceased.

GORHAM BACON, M.D.,
J. B. EMERSON, M.D.,
Committee.

A Chair of Hygiene at West Point.—The Sub-committee on Hygiene and Athletics of the West Point Board of Visitors recommends the establishment of a Chair of Anatomy, Physiology, and Hygiene. Such a chair already exists at Annapolis.

The Medical School of Maine.—The Medical School of Maine is said to be in prospect of an income of $8,000 a year from invested funds. For some reason the bequest has not as yet become available to the school.

New York State Medical Association, Fifth District Branch.—The Eleventh Annual Meeting of the Fifth District Branch of the New York State Medical Association will be held in Brooklyn on Tuesday, May 28, 1895. All Fellows desiring to read papers will please notify the Secretary, Dr. E. H. Squibb, P. O. Box 760, Brooklyn, N. Y.

The Late Dr. Henry Goldthwaite.—At a special meeting of the Medical Board of the City Hospital, held at the New York Academy of Medicine, January 17, 1895, the following preamble and resolutions were unanimously adopted:

Whereas, We have learned with deepest regret of the death of our revered colleague, Henry Goldthwaite, M.D.; therefore,

Resolved, That in the death of Dr. Henry Goldthwaite we have lost a valuable and useful friend. His heart was warm and benevolent; to the poor and suffering he was devoted and consoling. With the highest sense of duty, he never spared himself, but always met with manly courage the responsibilities of his position. He was a wise counsellor, a warm and valued friend, a colleague of acknowledged forethought and wisdom, and a man of inflexible honesty and pure, upright character.

Resolved, That we deeply sympathize with the widow of the deceased and the other members of the family; and that a copy of these resolutions be transmitted to them, and that they be published in the medical journals.

ALEX. W. STEIN, M.D.,
T. H. ALLEN, M.D.,
J. A. ANDREWS, M.D.,
Committee.

The Regulation of Medical Practice in Massachusetts.—The First Annual Report of the Board of Registration in Medicine has just been presented at the State House. The whole number of applications of all kinds received up to January 1st has been 4,390. The whole number of certificates issued has been 3,017. Of these, 2,817 have been issued to graduates, and 200 have been issued to practitioners of three years' standing; 294 applications have been rejected, leaving some to be accounted for. A large number of these are simply awaiting engrossment, and certificates will soon be issued. Every application received has been carefully investigated, and none has been rejected unless passed upon by the full board. A number of those recently received are now being looked up, and some among them no doubt will be found which should not be accepted. "Polk's Medical and Surgical Register" for the year 1893 gives the total number of practitioners as 4,012, classified as follows: Regulars, 2,646; homœopathics, 687; eclectics, 221; not belonging to the foregoing classes, 458. There are now four medical schools in this State which confer degrees in medicine.

Professor Chittenden's Cartwright Lectures for last year, published in the MEDICAL RECORD, are to be republished in book form in March next. The numerous applications for reprints have made this a necessity. Further information can be obtained by addressing Professor R. H. Chittenden, Yale University, New Haven, Ct.

The Hospitals of London treat annually in their outpatient departments 1,308,813; in their wards, 83,341. The total expenditures in 1893 were $3,499,315. In the last eight years the expenditures have increased 40.30 per cent., the incomes 14.419 per cent., and the patients about forty per cent. What will be the end? In ordinary commercial institutions it would be bankruptcy.

Foot-ball in England.—During the winter of 1893–94, more than twenty million dollars gate money was taken in, and this only takes into account the club matches. The wages paid to professionals amounted to four million.

New Hospital.—The Woman's Hospital, of Portland, Ore., was recently opened. The staff of physicians is as follows: For Diseases of Women, Drs. E. P. Fraser, William Boys, and E. F. Tucker; Diseases of the Nervous System, Dr. Everett Mingus; Obstetrics, Dr. A. W. Moore.

The Philadelphia Board of Health.—The Councils of the city of Philadelphia having appropriated $15,000 for supplying antitoxin, it is the intention of the Board of Health to establish a Bacteriological Laboratory.

Prize Essay on Tuberculosis.—Dr. Herman Weber, of London, has given the Royal College of Physicians $12,500 for the foundation of a prize to be offered every two or three years for the best essay upon tuberculosis.

The Pennsylvania State Board of Medical Examiners will meet on February 14, 1895, in Philadelphia, at the northwest corner of Broad and Pine Streets, to examine applicants for license to practise medicine in the State.

Medical College of Indiana —The Faculty of the Medical College of Indiana held a meeting December 14, 1894. It was decided to erect a new building at a cost of not less than $50,000.

New Amphitheatre.—The operating amphitheatre of the hospital of the Medical College of Virginia, at Richmond, has been remodelled and supplied with all the latest aseptic operating furniture and apparatus. This department is presided over by a trained nurse, whose sole duty is to care for the operating-room, prepare the patients, and assist at operations.

Army Medical School.—There are only two Assistant Surgeons in attendance at the current session of the Army Medical School as against seven in 1893–94. The decreased attendance at the session of 1894–95 is due to a reduction of the number of Assistant Surgeons, U.S.A., by recent act of Congress.

A Fin-de-Siècle Hospital for the Tuberculous.—A novel kind of hospital has been opened at Ormesson, close to Villiers, on the river Marne. One portion of the building is devoted exclusively to the treating of tuberculous children, and is separated by the whole length of the garden from the main structure. On the ground floor are the consulting and operation rooms, inhalation and bath rooms, and a bacteriological laboratory. The wards are supplied with ozone from leather bags. Sun and air baths are taken on a terrace furnished with comfortable couches for the purpose. Kerosene, turpentine, eucalyptus, and similar bactericides are mixed with the atmospheric air of certain portions of the building. There are no published results yet available, but the experiment, though by no means so sensational as some of those to which we have been recently accustomed, is of a decidedly interesting character.

The Society of the Lying-in Hospital of New York have formally opened up their new hospital at Seventeenth Street, corner of Second Avenue. The old hospital at Broome Street will still be retained as an emergency station. Heretofore the service conducted by this Society has been entirely an outside one, the patients being confined and taken care of at their homes. The new hospital enables the Society to add to the present outside service an inside one. The building is fitted up in the most modern manner to carry on a large obstetrical service, there being five wards with thirty beds, three examination rooms, and an operating theatre which has every convenience and appliance necessary for scientific midwifery. The attending physicians are: Dr. James W. Markoe, Dr. Austin Flint, Jr., Dr. J. Clifton Edgar, Dr. H. McM. Painter, and Dr. Samuel W. Lambert. The resident staff are: Dr. Maxwell H. Allen, Resident Physician, and Dr. Alfred Bleil, Dr. John Taylor, Dr. W. E. Ard, Dr. C. B. Young, Dr. John Reb, and Dr. S. J. Craig, assistants.

Prevalence of Diphtheria.—The following is a table showing the percentage of deaths from diphtheria on the estimated population during the years 1892 and 1893, as officially received from a few of our larger cities in this country:

	1892.	1893.
New York	0.08	0.10
Chicago	0.07	0.06
Philadelphia	0.13	0.08
Brooklyn	0.08	0.06
St. Louis	0.04	0.04
Boston	0.09	0.10
Baltimore	0.08	0.04
San Francisco	0.07	0.05
Cincinnati	0.09	0.05
Buffalo	0.06	0.05
Cleveland	0.07	0.04
Washington	0.07	0.04
Pittsburg	0.11	0.06
Milwaukee	0.16	0.08
New Orleans	0.02	0.03

It will be observed by this table that in 1892 the largest death-rate from this disease in fifteen of our largest cities, was in Milwaukee, Philadelphia, and Pittsburg, being 0.16, 0.13, and 0.11 respectively; and the smallest rate for the same year was in New Orleans, St. Louis, and Buffalo, being 0.02, 0.04, and 0.06 respectively. While in 1893 the largest rate was in New York, Boston, and Milwaukee, being 0.10, 0.10, and 0.08 respectively; and the smallest rate was in New Orleans, Washington, Cleveland, Baltimore, and St. Louis, being 0.03, 0.04, 0.04, 0.04, and 0.04 respectively. These figures are approximately correct.—Dr. U. O. B. Wingate.

Medical Testimony.—The President of the United States recently pardoned a prisoner undergoing sentence in the Jeffersonville Prison. The pardon was granted on a certificate from several medical men that he was incurably diseased. After release he boasted of his good health, whereupon an investigation was ordered and the prisoner was afterward examined by a representative of each medical college in the city, and the first report of the prison physician was corroborated. It was found that he had a cavity in one lung, had hectic, pulmonary hemorrhages, night-sweats, loss of flesh, elevated temperature, and considerable cough.

Lancaster (Pa.) City and County Medical Society.—The regular meeting of the Lancaster City and County Medical Society was held January 2d. The election of officers resulted as follows: *President*, Dr. T. J. Wentz, New Providence; *Vice-Presidents*, Drs. J. A. E. Reed and J. F. Trexler; *Recording Secretary*, Dr. William Blackwood; *Corresponding Secretary*, Dr. Walter Boardman; *Treasurer*, Dr. G. R. Rohrer; *Censors*, Drs. A. M. Miller, Bird in Hand, William Comptom, and M. L. Davis.

Reviews and Notices.

A Text-Book of Volumetric Analysis. With Special Reference to the Volumetric Processes of the Pharmacopœia of the United States. By Henry W. Schimpf, Ph.G. New York: John Wiley & Sons. 1894.

The book is designed for the use of pharmacists, although physicians will equally profit by its perusal.

The first portion of the book contains the principles of volumetric analysis, which are given in a thorough and concise way. The latter portion is devoted to descriptions of such special analytical processes as are used by the pharmacist or physician. Chapter XIV., "Sanitary Analysis of Water," contains a minute description of the way water should be examined and analyzed. We mention the following excerpts from the text:

"In collecting samples of water great care must be exercised in order to secure a fair representation of the water and to avoid the introduction of foreign matters. The samples should be collected in clean glass-stoppered bottles having a capacity of from two to five pints."

"Color: This may be taken by looking down through a column of water in a colorless glass tube about two feet long, standing upon a piece of white paper. A comparison is made with a second tube containing distilled water."

"Odor: Three or four ounces of water are placed in a small flask fitted with a cork through which is passed a thermometer; the flask is placed in a water-bath and heated to 100° F. The flask is then shaken, the cork withdrawn, and the odor immediately observed. In this way satisfactory and uniform tests are obtained, and a practised nose can frequently detect pollution."

This book deserves highest recommendation.

Heart Studies, chiefly Clinical. Vol. I. The Pulse Sensations. A Study in Tactile Sphygmology. By William Ewart, M.D. Cantab.; F.R.C.P. London, M.R.C.S. Eng.; Physician to St. George's Hospital, and to the Belgrave Hospital; Examiner in Medicine at the Royal College of Physicians of London, etc. Pp. xxiv., 486. London: Baillière, Tindall & Cox. 1894.

This substantial volume is a plea for the study and practice of tactile sphygmology. The author is well known to our clinicians through his little books, "How to Feel the Pulse" and "Cardiac Outlines," republished in this country. Regretting the relative neglect of the valuable clinical information to be obtained by the educated touch of the physician, as compared with the elaborate detail and mechanical accuracy of the sphygmograph, he sets himself at work to bring the results of physiological research and bedside observation of the digital examination of the pulse into harmony with other methods of investigation, as they are practised in the last decade of the nineteenth century. Taking as his text the carefully described work of Henri Fouquet, the skilful physician of Montpellier, he shows that neither his methods nor his observations have obtained due recognition. While it is evident that Fouquet recorded what he felt, it is by no means certain that some of his recorded observations were not those of errors into which his faulty methods led him. Notwithstanding this, we believe that he did not merit the criticisms which Broadbent has, within recent years, applied to his work. The value of tactile as compared with mechanical sphygmology is certainly very great. In spite of mechanical perfection, in spite of the earnest work of numerous experimenters, the sphygmograph is to-day hardly to be considered as a necessary instrument in the equipment of the physician. The sphygmograph registers variations of pressure—within limits only—without defining their absolute value, while it does not claim to judge of the volume of the artery at the various stages of the pulse waves; nor does it supply us with any data as to the modifications in the rapidity of the blood stream. The author reviews the work of von Kries, of von Frey, and of Roy and Adami, and endeavors to reconcile their conflicting views based upon work with various mechanical devices, and at the same time to bring their results into harmony with his conclusions derived from a careful study of his tactile sensations. That he has admirably succeeded, anyone who will thoughtfully read his book must admit. Stating that the pulse-beat, here termed *ictus*, is produced by the ascending wave of rebound from the periphery, he prescribes the correct method of best appreciating it and its variations, discusses its physiological and clinical modifications, and finally harmonizes his deductions with those reached by the best workers with the sphygmograph. The author has chosen a neglected field, for, although physicians have felt the pulse they have, either from lack of education or from indifference to what has become a routine practice, failed to fully appreciate the information which it may convey. The subject is presented clearly and in an interesting manner. The typography is inviting and singularly free from errors. Of the many books which come to our table we would select this as one of the most important for the careful study and the intelligent practice of the conscientious physician.

A Dictionary of Medicine. Including General Pathology, General Therapeutics, Hygiene, and the Diseases of Women and Children. By Various Writers. Edited by Richard Quain, Bart., M.D. Lond., LL.D. Edin., F.R.S.; Consulting Physician to the Hospital for Diseases of the Chest, Brompton, and to the Seaman's Hospital, Greenwich, etc. Assisted by Frederick Thomas Roberts, M.D. Lond., B.Sc., Physician and Professor of Clinical Medicine, University College Hospital, etc., and J. Mitchell Bruce, M.A. Abdn., M.D. Lond., Physician and Lecturer on the Principles and Practice of Medicine, Charing Cross Hospital, etc. With an American Appendix by Samuel Treat Armstong, M.D., Ph.D., Visiting Physician to Harlem, Willard Parker, and Riverside Hospitals, New York. Two vols., royal 8vo, pp. 1260 and 1305. New York: D. Appleton & Co.

The present work was first issued in a large single volume in 1882, and now appears so much enlarged that two volumes are necessary to compass its scope. The type has been enlarged and its typography proportionately improved. The number of pages has been increased from 1834 to 2518; 43 new illustrations have been added, making 181 in all.

As the title indicates, this is a Dictionary of Medicine, with the subjects arranged alphabetically and treated by numerous well-known authorities. The condensations under the respective headings are, as a rule, admirable for their perspicuity and practical character. The essentials of information are given in such terseness and reasonable completeness as to leave nothing to be desired on the part of the students to turn to the different subjects for ready and useful information. The progress of medicine during the past decade, unprecedented as it has been, necessitated much revision and modification of views, more especially since bacteriology, with its notable discoveries and significant suggestions, has mapped out new lines for the study of the causes, and new methods for the treatment, of various infectious diseases. From such standpoints the work is essentially different in quality from its predecessor, being as it is entirely up to date on all matters pertaining to the progressive medicine of to-day. The various articles are virtually monographs in themselves, with the great merit of being shortened to

the smallest possible limits. Each is signed by the author, giving it the directness and authority so much needed in a work of this character. It would be impossible, with the immense number of topics treated, to discuss the relative merits of each. On the whole we must be forced to admit that the different amounts of space allotted to different topics are so nearly apportioned to their respective importance that criticism gives place to commendation, and invidious comparison to necessary consistency. If anything the illustrations, excellent and well selected as they are, might have been more numerous. But here again a more or less arbitrary limit would always be necessitated. The talented American editor has done his work faithfully in an appendix to each volume, and has in a great measure made the work more acceptable to the profession in this country than would otherwise have been the case. His notable and creditable contributions have been on the lunacy laws of the United States, the milk cure, the quarantine laws, and serum therapeutics, and a full account of the different mineral springs and health-resorts of this country.

Leitfaden der Gerichtlichen Medicin, für Studirende und Aerzte. Von Dr. K. J. Seydel, a.o. Professor an der Universität und Gerichtlicher Physicus in Königsberg, i. Pr. Berlin: S. Karger. 1891.

Forensic medicine has been a strangely neglected science in Germany up to within a comparatively recent period, so that the author of this book had a fresher field to work than most writers on medical jurisprudence in other lands. The present work is by no means exhaustive, having to do chiefly with the signs of violent death in adults and infants. Over two hundred and fifty out of the two hundred and eighty pages of the book are given up to this subject, which is very fully and satisfactorily treated. The publisher's part of the work is well done, the book being clearly printed with new type on good paper.

The Medical Register of New York, New Jersey, and Connecticut, for the Year commencing June 1, 1894. By John Shrady, M.D., Editor. Vol. XXXII. G. P. Putnam's Sons. 1894.

This welcome and widely appreciated annual was somewhat delayed in its appearance in consequence of the fact that the enterprise "was begun much too late to insure speed in publication without too great a sacrifice of accuracy." When, however, we consider the evident painstaking to make this volume the model of its kind of varied and trustworthy information concerning everything medical in the lines of registration, and in all other matters wherein the medical profession of New York and the neighboring States are interested, we can congratulate the editor and society on the gratifying outcome. It has become so much the habit with the busy doctor here and elsewhere, whenever he wishes to be informed of medical men, hospitals, and other charitable institutions, nurses, medical organizations, civil and military, medical laws, etc., to go to the "Register" as authority, that it is always a desirable regulation for business to have this handy volume within easy reach.

Physician's Complete Account Book. Arranged by J. Marshall Hawkes, M.D., and R. Harlan Hawkes, M.D., New York City. New York: Peckham, Little & Co.

This is a well-arranged account book of about 7½ × 10 inches, with a lettered index in front. It contains spaces for 100 long and 650 short accounts, obstetrical record, etc. It is intended to answer for two years. The price is $3.00.

"**Physician, Wheel Thyself**" is the motto under which bicycle-makers are now appealing to the profession.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, December 20, 1894.

D. B. St. John Roosa, M.D., President, in the Chair.

Presentation of an Oil Painting by John Blake White, "Resuscitation from a State of Trance."—Dr. T. Gaillard Thomas made the presentation address on behalf of the donor, Dr. O. A. White. Dr. Thomas said it gave him pleasure to grant the request of his friend, Dr. White, and present to the Academy a painting by his father, one of the greatest artists of his native State, South Carolina. Mr. White was a man who had been ahead of the time in which he lived, and had strongly combated the three great vices of the South in the early part of this century—intemperance, duelling, and a lack of patriotism for the Union. He had painted a number of pictures that were widely known and dear to the American people. The picture presented to the Academy was an historical one, and represented a scene over two hundred years ago. A young woman had fallen into a trance and had been placed in a vault; two robbers had cut their way into the vault in order to secure the jewels, and, in trying to remove the rings from the fingers, cut the hand, and by this act resuscitated the young woman from her trance. This is the part of the scene represented by the picture. Dr. Thomas said that Dr. White presented the picture to the Academy for three purposes, viz., as an expression of the pleasure that he received from the Academy, to perpetuate the memory of his father, and to form a nucleus for an art collection in the Academy.

Dr. Roosa, in accepting the picture on behalf of the Academy, expressed the hope that others would contribute pictures that would add a new feature to the Academy, the nucleus of which had been started by Dr. White.

Report of Committee on Quarantine. — The Committee reported that it had done a great deal of work to secure the establishment of a National Board of Health, and that in all their efforts they had met with the approval of the profession. They had presented a bill to Congress, but the bill had not been reported. They expressed their belief that much would yet be accomplished in the matter.

On motion of Dr. Thomas, the Secretary was instructed to write a letter of thanks to the Chamber of Commerce for its financial and moral aid to the Committee on Quarantine.

The Influence of the Bicycle in Health and in Disease.—Dr. Græme M. Hammond read the paper on the above subject. (See page 129.)

In opening the discussion Dr. A. D. Rockwell stated that Oliver Wendell Holmes had once said "that if all the drugs were cast into the sea it would be better for man, but worse for the fish." He believed there was a curve of health, and that if men and women could only learn to eat and exercise correctly, the druggist's business would languish. He had used the bicycle for five years and wished that he had used it five years sooner. While he was an ardent advocate of bicycling he believed more evil came from indiscriminate riding than from any other exercise, for there was a fascination about it that was not found in walking, etc., and in the exhilaration of the exercise it might be carried to excess. He knew a young man who worked hard, and for two years had been in the habit of going on tours on his bicycle, often riding a hundred miles a day, until it began to injure him and he had to be more moderate. One advantage of the wheel was that it was easier to get persons to take exercise that way than by walking. No one should ride bent forward, or enough so to compel mouth-breathing.

Reduced His Age and Weight.—Dr. S. D. Powell said that he had begun to ride the bicycle in May, and since that time had reduced his weight twenty-six pounds and his age twenty-six years. He regretted that he had not learned to ride the wheel sooner, but thought it was because he had been prejudiced when in college. He had come from the South and had never seen ice, and was persuaded that if he would put on skates and start off without help no one would know whether he had ever been on skates or not. He tried it, and when he was asked to ride a bicycle he thought it was another trick. He had to administer a little parental discipline to his son who said, "Papa, you don't know anything about it; I'll bet you fifteen dollars you can't ride a wheel fifteen feet and not fall of." He won the fifteen dollars and had been riding the wheel since.

If a man stayed well within the limit of exercise it would do good, but if he went beyond it he must pay for it. The limit varied in different persons, and a healthy person could ride a bicycle as well as take any other kind of exercise. The exercise did not affect the legs alone, as any one could prove by riding until tired, when every muscle would be felt affected. As for the effect on the genito-urinary organs, no one who has diseased prostate, for instance, can irritate it without injury, whether that irritation be by riding the wheel, sitting, or anything else. There were fools and there always would be as long as the world lasted, but he did not believe in condemning a good thing because such persons abused the use of it.

Dr. William M. Polk said he was an amateur of the amateurs, and suspected that he was put down to discuss the paper because he and the chairman had at one time planned to learn the pleasant exercise together. He was induced to take up bicycling by the hope of long life and much joy. The long life was yet a question of time, but as for the much joy, he wanted to say that it was not altogether unalloyed, for the wheel sometimes proved to be an unruly beast to ride. He had suggested bicycling to some of his patients with favorable results, and he believed there were some female diseases that would be benefited by it. He thought it would be especially beneficial in dysmenorrhœa.

Dr. Frank Van Fleet gave a short history of the bicycle, and said that he believed the "safety" would do much for the mental and physical development of the race. He thought the best time for exercising on the wheel was early in the morning, while the natural scenery was so inviting and inspiring. The exercise was evidently a healthy one, and the ridding the system of so much waste matter by means of the perspiration was very beneficial. If bicycling had had the same effect on him that it had on Dr. Powell he would surely have to give it up, for he had too much trouble now on account of his youthful appearance and light weight. Fortunately he had gained twenty pounds during the last two years.

Dr. S. S. Burt said he must disagree with Dr. Van Fleet on the five o'clock question, for he did not believe in so much exercise before breakfast. One of the main advantages of bicycle riding was that it was so attractive, and that a man would take exercise in this way when he would not by walking.

Dr. H. Holbrook Curtis thought it was important to have the throat and nose examined, as often trouble came from mouth-breathing. No exercise should be undertaken without the mouth being closed. He thought leaning forward in riding the bicycle was caused by low handles; that women rode low saddles for the convenience of getting on and off, but if they were to ride with the saddles higher there would be no trouble from irritation of the genito-urinary organs, and they would not suffer from backache.

Transmission of Advertising Matter through the Mails.—Dr. A. Jacobi offered the following resolution, which was adopted: That medical books, pamphlets, and circulars, the contents of which are of a character not proper for general and indiscriminate perusal or circulation, should not be admitted to or transmitted through the mails unless enclosed in sealed envelopes or wrappers, and prepaid at letter rates of postage, unless addressed for delivery to or in care of physicians, surgeons, medical schools or colleges, or students in such schools or colleges, or to dealers in medical publications, and directed to them as such.

The Academy requested Dr. Jacobi to present the above resolution to such other medical societies as he should see fit, and to secure their indorsement of the same.

SECTION ON GENERAL MEDICINE.

Stated Meeting, December 18, 1894.

W. H. Porter, M.D., Chairman.

The Use of Vaso-constrictors in Cardiac Disease.—Dr. Reynold W. Wilcox read the paper of the evening on the above subject. (See page 141.)

Opposed to Whipping up a Weak Heart.—In discussing the paper, Dr. Charles E. Quimby said that he was forced to differ from the author of the paper as to the means of securing compensatory hypertrophy of a weakened heart. It would not do to put the heart to doing more work when it was already overworked and was failing from that overwork. An increased amount of work might be the treatment for a fatty heart, but he did not believe in the principle of increasing the work of an already weakened heart to make it hypertrophy. His treatment of a weakened heart was to secure as much rest for it as practicable. When the vascular tension was low and nutrition of the cardiac muscles impaired, the vaso-constrictors were indicated. Dr. Quimby said he had hoped the author would say something about valvular lesions. Eight years before he had begun the use of the pneumatic cabinet, had studied the effect of the alternate pressure, and was convinced that it gave more relief than drugs.

Dr. W. E. Porter said that as the nutrition of a part was secured by the blood that passed through the capillaries of the part, it was expedient to spread that surface out and not to force the blood through too fast, else the desired nourishment would not be secured. His experience had been that the vaso-constrictors shut off the blood-supply by driving it through the arterioles and capillaries too fast. He thought that digitalis was useful when the blood was largely on the venous side, for it was useful to take the larger volume of blood on the arterial side. Dr. Porter said he agreed with Dr. Quimby, that it was a bad thing to whip up a weak heart.

Dr. William M. H. McEnroe said he hoped to hear more stress put upon the use of the nitrites. He had used nitro-glycerine a great deal in his own case, and was of the opinion that digitalis was not the proper thing without it. Fifteen years before he had begun to take digitalis and found that it increased his nervousness, and he felt worse until Dr. Loomis told him to use nitro-glycerine also, when he found that this counteracted the bad effect of the digitalis. He had also used nux vomica and strophanthus, but at no time left out the nitro-glycerine.

In concluding, Dr. Wilcox said he agreed with Dr. Quimby, that it was a bad habit to whip up a weak heart, but he was of the opinion that the only way to compensate the heart was to give it more nutrition, and it was the slow blood-current that failed to provide the necessary nutrition. There was also the clinical fact that by increasing the heart work the heart became hypertrophied. Dr. Wilcox said the plea of the paper was that by the use of digitalis the pulse-rate could be controlled; that the effect on arterial obstruction could be easily cut out; that by the vaso-constrictors work could be increased, but was subject to the nitrites.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

NEW YEAR'S HONORS—SIR RUSSELL REYNOLDS—SIR J. E. ERICHSEN — ANTITOXIN — DOUBTS—CLAIMS TO PRIORITY—SUPPLIES—OYSTERS AND TYPHOID—NEW SOCIETIES—MEETING AT COLLEGE OF SURGEONS—THE PRESIDENCY—POISONING BY SOUP—PROFESSOR BURDON SANDERSON—DEATH OF LADY PAGET—ABUSES OF CLUBS—PAY-WARDS—ILKESTON OFFICERSHIP OF HEALTH—SIR JOSEPH FAYRER.

London, January 4, 1895.

According to custom, some honors have been distributed by the Queen at the opening of the New Year. Among them Dr. Russell Reynolds and Mr. Erichsen receive baronetcies. Your contemporaries are jubilant at this and loud in their praises of the favored recipients. It is, however, a very moderate appreciation to the profession which her Majesty's advisers have thus shown, for equal honors are showered on very different persons. Sir Russell Reynolds will undoubtedly maintain the honored position in the profession he has so long held. Yet, while the journals are emulating each other in his praise, I am old enough to remember that in his early days he was subjected to one of the most savage of journalistic onslaughts, and there were some who predicted that the doors of the College of Physicians would be closed against him. Now, there he is the President, and all delight to honor him. So much for above a quarter of a century's honorable conduct and the exemplification of high character. Still it is funny to meet some of the young bloods of the journals who think they know everything, but who have never heard the episode of their predecessors' blunder over Russell Reynolds.

Erichsen's surgery is as well known on your side of the Atlantic as here, and no doubt his successful career is familiar to most of your readers. This is now crowned with the distinction conferred, and everyone seems pleased with the selection for the surgical baronetcy.

Antitoxin still holds the field as the chief subject of medical conversation. The reports continue favorable, and there is in some quarters not a little enthusiasm. Still here and there cautious men are observed to be silent, or merely express a hope that the tuberculin disappointment may not be again experienced. One or two physicians I know are more than sceptical from clinical observations, but the enthusiasm of the majority silences criticism. When German authorities have fully discussed the matter, their differences will probably be repeated here. I learn from correspondence that O. Liebreich and several others are antagonistic to serum therapeutics *in toto*, Gottstein and E. Hahn are severe critics of the statistics published, while Baginsky and others hold to their clinical observations in proof of the value of the treatment. As the criticisms of foreign physicians become more widely known, I have no doubt not a few here who are unconvinced will become bold enough to speak out, and their doubts will have to be met. I may add that not a few, especially among the general practitioners, who have had no opportunity of using the serum, profess to hold themselves in a waiting attitude, and though apparently their hopes are not very high, of course they would rejoice at proofs of decisive success.

It is curious to notice that, as in the case of many discoveries, great or small, questions of priority arise. Professor Babes has put in a claim, on account of his immunizing animals to tetanus and hydrophobia, to the credit of originating serum therapy. He admits, however, Behring's claim as to diphtheria. On the other hand, Spain claims the honor on behalf of Professor Ferran, who is said to have immunized animals against diphtheria and published his results in April, 1890. This certainly looks like a serious claim, and if fully substantiated will redound to the honor of the Barcelona school. No one will begrudge Spain such a sign of her reawakening to scientific progress.

The supply of serum is still very short in London, but we are promised more at an early date. The demand will probably more than keep pace with the supply for many weeks to come. It is, therefore, perhaps wise of general practitioners to wait patiently for the results of full trials in hospitals.

We have an "oyster scare" on hand. It is alleged that the mollusk has conveyed, in several instances, typhoid fever to its consumer, and as this disease is more than usually prevalent just now among the well-to-do, the allegation is disquieting—especially considering the outbreak on your side of the water, of which I lately learned particulars from your columns.

More societies—there seems to be no class but desires to have one to itself. The qualified assistants and junior practitioners are now organizing themselves into a society. So too are the masseurs and masseuses, the occasion of the latter effort being the futile attempt of the *British Medical Journal* to persuade the police to follow up its revelations—which revealed—nothing.

An attempt is also being made to form a new society of members of the College of Surgeons. The defunct society did something to excite attention, but its methods were unsuccessful. The new society may avoid its errors, but at present does not look very strong, and I fear is hardly likely to cope with the selfishness of the Fellows, even while the latter's forces are as disunited as they showed themselves but yesterday.

January 12, 1895.

The meeting of the Fellows of the Royal College of Surgeons was, as I predicted, of very little interest to those outside the position of fellowship, and even those within seem to expect but slight results; for some time elapsed before the necessary quorum of thirty could be completed, and only sixteen in addition ultimately put in an appearance. The Council did not consider it desirable to test the opinion of Fellows except by motion at the half-yearly meetings, but an independent canvass had been taken as to the mode of electing the President. This canvass does not show any strong feeling on the matter, as out of 1,000 papers sent out only 468 were returned, and of these 50 were invalid. Among the returns 150 expressed satisfaction with things as they are and the others are willing to try some change. The proposal to request the Council to appoint a joint committee of councillors and other Fellows to consider the question of a new charter, was carried by twenty-two to fourteen, but the past affords little ground for anticipating compliance. It matters little, however, to the bulk of the profession who are only members, and if they obtain no voice in their college, the President will remain in fact president of the Council, but scarcely a president of the complete college.

I mentioned last week that oysters had been suspected here as well as on your side, of conveying the poison of typhoid fever. To-day the *British Medical Journal* publishes a communication from Sir W. Broadbent recording half a dozen cases in which he could trace the disease to no other probable source. An editorial remarks that on previous occasions a similar suspicion has been entertained—once at Dublin in 1890—and further, that in 1880 Sir C. Cameron brought before the annual meeting of the association cases of grave intestinal disorder apparently produced by oysters.

In connection with this subject other forms of food poisoning, whether due to ptomaïnes or other causes, must attract more attention. A painful case occurred in the Christmas week, when about one hundred persons in a village were simultaneously attacked by

purging, vomiting, and intense prostration. No cause could be traced except that the patients had partaken of soup distributed in charity some two days previously. The case has been carefully investigated by Professor B. Hill, medical officer of health, but analysis discovers no poison, and it is suggested that the soup may have been contaminated by down-draft from a ventilating pipe near the base of which it stood for the night.

Dr. Burdon Sanderson has been appointed to succeed Sir Henry Acland as Regius Professor of Medicine at Oxford. To some of the younger men in the profession he is so exclusively known as a physiologist that they may fancy it is putting the square man in the round hole. But their elders can enlighten them on the pathological and even clinical work done in earlier days by the professor. Still his reputation as a physiologist has cast every other qualification into the shade ; so that we may well say that the scientific basis of medicine, rather than its practical application, is the justification of an appointment which will probably prove a success.

Only last year I congratulated Sir James Paget on his golden wedding. It seems but such a short time ago, and now I have to express the sympathy of all his brethren with the great loss he sustains in the death of his wife. Lady Paget died on the 7th inst., in the eightieth year of her age.

Ireland has taught us some strange lessons, among them the art of boycotting. We may yet see a shadow of this in our calling, but the gentler method will be tried first. Just now there is a revolt in Cork against some abuses of the club system. It is spoken of as a doctors' strike, though that is scarcely the correct term. The facts appear to be that men of good income, as much as £500 and upward, even to £1,000 per annum, have been mean enough to join the Odd Fellows and other clubs, and expect the doctors to attend them as if they were artisans. At last the doctors have had the courage to unite and refuse. Only one doctor in all Cork remains outside the movement to prove that the profession is not united. The others will perhaps know how to treat him. Certainly he deserves to be "sent to Coventry," as Englishmen express it, but Ireland may yet have a better lesson for us. There is, I learn, some tall talk among secretaries about setting up some new doctors in the city. If any young men disgrace their cloth so far as to fall into such a snare, they will deserve no pity if they find themselves to be outcasts of society.

The question of pay patients in hospitals is far from settled, and the honorary staffs who give them countenance will probably repent their folly. There are pay wards at Guy's, and a recent attempt to secure for them more support is giving offence. Even Guy's men may have a very unpleasant experience if they persist in conduct which will assuredly alienate some of their best friends. General practitioners will some day unite to treat all consultants who injure their position in the manner directed in the ethical code.

The medical officer of health of Ilkeston was too advanced a sanitarian for the town council. He had worked for £30 per annum, and later for £50. He is superseded by a member of this most respectable town council at £100. This scandal shows that generally some one will step into an underpaid office, and further, that to look for an appreciation of medical service as part of the reward of work is downright foolish. Better far would it be not to accept such underpaid appointments. Then the public might learn the value of services they now almost despise.

Sir Joseph Fayrer retires from the presidency of the India Office Medical Board, in accordance with the age rule. He carries with him the good-will of all his brethren, as well as the admiration of all who know the great services he has rendered in his long career. He is to be succeeded in the office by Brigade-Surgeon Lieutenant-Colonel W. R. Hooper, of the Indian Medical Service. We may hope the clumsiness of his title will open the eyes of the authorities to the absurdity of these compound designations.

HYPNOTISM AS AN EXCUSE FOR CRIME.

To the Editor of the Medical Record.

Sir : During the past year many persons have been accused, by perpetrators of different crimes, and also by others, some of whom are apparently mentally deficient, of hypnotizing them. And persons so accused have been imprisoned, and one has even been sentenced to death. Are we returning to the good old days of the Salem witchcraft? Some one is responsible for this state of public opinion, and it seems to me that if the medical profession is not directly responsible, it is negatively so, in not protesting against a thing which, although absurd and irrational, is full of such dangerous possibilities. Now, if hypnotism were but another name for that influence which all persons have over those mentally weaker than themselves, an influence which does and always has existed in every rational human being, then we must admit that hypnotism is the starting-point of a great many crimes. And while the person who uses his influence to cause or induce another to commit a crime is and always has been considered punishable, the person so influenced is held to be none the less so. But if by hypnotism is meant some particular power delegated to or vested in some particular person or persons, and that every other man in the universe does not have the same power in a greater or less degree, and if it is supposed that the person hypnotized does not act more or less of his own free will or have full knowledge of all his acts ; or if he is supposed not to be able to distinguish between right and wrong, but is thought to be under the control of the will of the hypnotist, and sometimes to remain so, unless released by some "magical" words by the operator, then I must say that I do not believe a person was ever hypnotized. On the contrary it seems to me the veriest humbug. What will be the result of this hypnotic excuse if allowed to continue? There can be but one, you will see embezzlers, murderers, and criminals of all kinds plead "hypnotic control," and many an innocent person will suffer. The people look to the medical fraternity for light in such things, and they should have it in the shape of an emphatic denunciation by the profession and press. That those who believe in and practise hypnotic suggestion are for the most part honest I haven't a doubt. But I believe that they mistake that influence which is born in every person and which has existed since the beginning of the race for some wonderful power which they are pleased to call "hypnotism."

West Pawlet, Vt.

CASTIGATION FOR CRIME.

To the Editor of the Medical Record.

Sir : In the editorial columns of the Medical Record for January 19th an article appears entitled, "The Threatened Revival of the Whipping-post," in which some of the statements made are so at variance with the facts in the case that I beg you to allow me the space to answer and comment upon them.

In the first place the subject for discussion at the meeting which is referred to at the Academy of Medicine, January 9th, was not the whipping-post, as every member of the Academy who received a notice of the meeting knows, and that phase of the subject was not alluded to in my paper except in connection with its present use in Delaware. Moreover, I distinctly stated that with my present light and opinions I did not favor it, but favored the system of corporal punishment

which had been used with so much success at Elmira. What Mr. Gerry and others may or may not have said that was not suggested in the paper of the evening as a subject for discussion, was a side issue, and should not be permitted to obscure the main issue. I may or may not be in favor of punishing criminals with a whip; I may or may not be in favor of a whipping-post, either public or private (which I am not and so stated with the utmost distinctness); the contention of the paper as I stated at the close of the discussion, was for the principle of corporal punishment for crime, especially beating and violently abusing women and children. If that principle is allowed the details can be worked out afterward.

Again, what can be the meaning and coherence of the following: "He (Mr. Gerry) thinks that the only thing these persons fear is pain, and that a flogging will accomplish far more than imprisonment, though the former is not to supplant it or supplement the latter." The next two sentences are still further confusing and lead one to wonder whence the information suggesting them could have been obtained: "One cannot easily conceive the mental complexion of a man who would prefer years of imprisonment to a single flogging in private (it being explicitly provided in the proposed bill that only a physician and the prison warden shall be present when the flogging is given). When we recall further that the criminals in question are notoriously anæsthetic, paying little heed to physical injuries that would be exquisitely painful to ordinary persons, and constantly receiving such injuries in bar-room brawls and street-fights, it becomes still more open to doubt whether the prospect of receiving "forty lashes at most" in private will deter one of them who, in a moment of passion or while intoxicated, is tempted to beat his wife or to commit rape or sodomy (these being the crimes chiefly had in mind by the advocates of the proposed measure)."

The matter becomes hopelessly involved and contradictory, unless we turn to Mr. Gerry's bill and see what it actually does recommend. Its words are as follows: "Whenever a male person shall be convicted of a felony consisting in or accompanied by the infliction of physical pain or suffering upon the person of another, the Court wherein such conviction is had may, in his discretion, in addition to the punishment now prescribed by law for such felony, direct the infliction of corporal punishment upon such convict, etc."

As to the further statement in your editorial that there is plausibility in the recommendation of one of the speakers at the meeting in question, that the whipping-post might accomplish the best results if used for the correction of minor delinquencies rather than major crimes, there is an inherent admission of the principle for which I am pleading, that corporal punishment as a penalty is justifiable and desirable.

It is not urged that such punishment be inflicted as "a vengeful application" as you seem to think is advocated, nor, on the other hand, can the retributive element to which you refer be entirely omitted; it is an element which necessarily enters, more or less, into the idea of all punishment, whatever its nature may be.

We can stand by the facts; corporal punishment checked garroting in England in six months; since it was discontinued at Elmira, fighting has increased among the inmates of the Reformatory fourfold, and other facts equally convincing could be furnished if necessary. Every man has a right, in this country at least, to his opinions, and to express them on proper occasions. I am willing to concede honesty of purpose to those who differ with me on the subject in question, but admitting the existence of wife-beating and similar forms of cruelty, and the inefficiency of present methods of treatment, if you refuse to inflict corporal punishment and suggest nothing as a substitute, you will admit that you are countenancing a grievous wrong and consenting to a great injustice.

To advocate an unpopular cause is not always easy or agreeable, but if it is right, or if one thinks it is right, other considerations should have very little weight.

ANDREW F. CURRIER, M.D.

NEW YORK, January 23, 1895.

THE LATE PROFESSOR LOOMIS AS A TEACHER.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the obituary notice of Professor Alfred L. Loomis in to-day's MEDICAL RECORD, three of his characteristics are made justly and sufficiently prominent, namely: 1, his value to "many of the medical circles in which he was such a leading and active figure;" 2, his authorship of medical essays and text-books; and 3, his rare business qualifications. A fourth characteristic is not dwelt upon, perhaps because it was universally admitted and generally admired and applauded, namely, his excellence as a didactic lecturer.

Who, of the thousands of students who have enjoyed the pleasure, and I might say luxury, of having listened to his even, earnest, often eloquent, and the never-tiring flow of his never-flagging, clear-cut, clean, and withal plain and easily comprehended, oratory—who of all these men can have forgotten the lasting benefit they got from it? Who of all these men can have forgotten the magnetic fire of his eyes as he portrayed for them the substance of their future studies? And who of all his listeners have forgotten the firmness of his grip on the never-missing stick or pointer, as though it were a wand from fairyland to which he owed all the power and charm of his way of teaching?

Loomis was a most extraordinary didactic lecturer, and as such a great teacher. He never taught us any nonsense. And though his teaching was free from egotism, it was marked by a characteristic individuality. He used to say that he tried to find a peg for us to hang our hats on. Indeed, all his teaching, at his didactic lectures, at his clinics, and in his physical diagnosis classes, was marked by what Kant has called "a certain correct scientific taste," which guards against the excesses of a scramble for what is new, and confirms us to habits of safe and guarded judgments, besides developing a rational trustworthiness that comes from a full and circumspect experience.

An old German proverb says, "The Pope himself can do no more than his best." I am sure, all those who had the good fortune to get their first lessons of theoretical and practical medicine from the eloquent lips of Professor Alfred L. Loomis, will always think of him as having done his best for them, and as having done that best nobly, aye, beautifully too.

Yours very respectfully,

ADOLPH RUPP, M.D.

NEW YORK, January 26, 1895.

Examining Students in their Mother Tongue.—A new rule has lately been adopted at the University of Edinburgh, under which a candidate may be examined in his native language. Under this rule a Japanese medical student, not long since, had a paper sent him in his own language at a medical preliminary examination. For two years or more Japanese students entering Harvard University have been permitted to substitute Chinese for Greek in their preliminary examination.

New Sewerage System in Mexico.—Among the measures contemplated and under way for improving the sanitary condition of the City of Mexico, is one for increasing the rate of flow through the sewers. This project, the cost of which will be about $25,000, calls for the building of some twenty-five windmills in different parts of the city to rotate paddle-wheels in the sewers, and quicken the current to three feet per second.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 26, 1895.

	Cases.	Deaths.
Tuberculosis	91	120
Typhoid fever	10	5
Scarlet fever	102	11
Cerebro-spinal meningitis	3	4
Measles	65	4
Diphtheria	228	34
Small-pox	3	1

The Necessity of a Higher Estimation of Tooth and Mouth Hygiene.—At a meeting of the Berlin Society of International Medicine Dr. P. Ritter recently made an address on this subject. He pointed out how the mouth was the starting-point and breeding-place of germs. How he had frequently seen workmen and workwomen lose their places on account of want of the incisor teeth or foul breath. Continuous toothache frequently led steady men to the brandy bottle for the relief of pain. In pregnancy the necessity for attention to the mouth and teeth was especially great, as women at these times so often suffered from tooth- and face-ache. Probably the cause lay in excessive nausea present leading them to neglect the care of their teeth, so that the secretions became acid and favored caries. Women should be recommended to brush their teeth three times a day after the third month, using some astringent fluid and an alkaline tooth powder, and a moderately hard brush. On the basis of many years' experience, he held the following to be demanded: The appointment of experienced dentists to examine the mouths of all school children at stated intervals, the parents to be informed of the result of the examination, and left to have the treatment required carried out privately or through institutions. The appointment of dentists for the poor. Delivery of addresses in the Volksschulen on the importance of the masticatory apparatus and the toilet of the mouth. Dissemination of printed instructions on the toilet of the mouth to the whole of the poor population.

Grand Old Men of Medicine.—Medical men have, as statistics show, a shorter average lease of life than members of the other liberal professions. The late Dr. Bisset Hawkins's exceptional span of years is discounted to some extent by the fact that for half a century he had not been engaged in professional work; it is not probable that at any period of his career he was ever heavily burdened with the cares of active practice or that he felt the stress of the struggle for existence. There are, however, a few instances of longevity in working members of the profession which go some way to bring our average of life up to a fairly respectable level. Not to mention Dr. G. Paris, formerly physician to Louis Philippe, who has just passed away at the age of ninety-three, the medical profession of Valencia, in Spain, has been celebrating the birthday of the oldest member among them, Dr. Salvador Lopez Català, who completed his ninety-first year on November 9th. Dr. Català was in active practice till less than four years ago. An American paper states that Dr. Hiram Corson, of Montgomery County, Pa., is the oldest practitioner in the United States who is still in harness. He is now ninety, and he has been in practice since 1827. Dr. Corson is still in excellent health, and preserves his powers of body and mind to a remarkable degree. He is now writing his personal recollections of the anti-slavery movement, in which he took an active part, having assisted many a runaway slave to escape by the "underground railroad." The New York Medical Record, however, enters a claim for what it calls the long-distance championship on behalf of Dr. Hull Allen, of Milford, Ct., who was born on May 16, 1798, and is now consequently well on in his ninety-seventh year. We have older practitioners than either of these American "champions" in this effete old world in the persons of Dr. Boisy, of Havre, who, we believe, was in practice, and could even go upstairs to see his patients in their bed-rooms, after he had completed his century of life; and of our own, Mr. W. Salmon, of Penllyne Court, Glamorgan, who became a Member of the Royal College of Surgeons in 1809, and is now in his one hundred and fourth year. To all these grand old men of medicine we wish a happy New Year, and many of them.—*Lancet.*

A Homœopathic Medical College in Court.—In the suit in equity filed by the Washington Homœopathic Medical Society, asking for an injunction against the National Homœopathic Medical College, the plaintiff on October 9th filed an amendment and supplemental bill. After reciting the fact of the filing of the original bill the plaintiff states that the defendants were served with process, and although they made emphatic declarations through the public press of their desire to be heard, and to vindicate themselves, they have never answered the bill, and have sought to delay their answer by raising a technical objection to the form of the summons, insisting that the District of Columbia corporation is entitled to sixty days within which to answer, and the defendants have never made the slightest effort to bring the cause to a hearing. In defiance of the outraged sentiment of all the reputable physicians of the District of Columbia, the bill goes on to say, the defendants, or one of them, have, during the past year, pretended to conduct a homœopathic medical college in which they profess to give instruction in the science of medicine. The plaintiff claims that the defendants have made no addition to their equipment nor any improvement in the *personnel* and standing of their so-called faculty; that they succeeded by unscrupulous advertisement in deluding into attendance some persons honestly desirous of obtaining a medical education; that in at least one case it has granted a diploma to a person who has actually studied medicine for not exceeding seven months in the alleged college; that in another case it has granted a diploma to a person who was forced out of a recognized and respectable medical school because of absolute inability to pass any examination, and that the defendants, for the purpose of attracting students, have continued to advertise, as members of the faculty, the names of physicians who had previously positively refused to be identified with the college or to allow their names to be used in connection with it. The court is asked that the defendants, pending the suit and perpetually, may be enjoined from conducting said alleged college.

A New Method for the Treatment of Wounds.—We have had the opportunity, says the *Medical Press*, of studying the new treatment of wounds devised by Dr. George Stoker, and find it to start from the original idea of using the stimulating effects of oxygen on a granulating surface; the *primâ facie* idea not being one of antisepticism. The method consists in keeping the part of the limb on which the wound or ulcer is present in an air-tight wooden box, the upper part of which is glass, and which, at the extremity where the limb enters, is closed by an India-rubber funnel fitting to the limb and kept *in situ* by a turn of a Martin's bandage. To this box are connected three India-rubber tubes about three-sixteenths of an inch in diameter. Through the first, the attendant at stated intervals pumps in warm air by a plan closely resembling that used in a Higginson syringe, the warm air, however, passing through two bottles, one containing Condy's fluid and the other lime-water, while in a glass portion of the

tube itself it traverses menthol and medicated wool. Through the second tube the oxygen is carried in. The third tube is utilized to carry off any impure air into a bottle of Condy's fluid. The treatment is commenced by pumping in the warm air for about three minutes; this is done first, as it is found that the pure oxygen is too stimulating. Next the oxygen is turned on, and this is continued at a very low pressure, and not even shut off when the warm air is pumped in again at intervals of a quarter of an hour; pain, which is increased by dryness, is relieved by this method. The ulcerating surface is dressed twice a day with dilute warm boracic solution, with which it is gently syringed and the scabs removed, the box, of course, being taken away during the dressing. The treatment necessitates the constant attention of a nurse, who has to a certain extent to be specially trained. The cost is about one farthing per hour, but this probably, Dr. Stoker asserts, could be considerably reduced. Through the courtesy of Dr. Stoker we were enabled to see a patient under treatment; the subject certainly was not a favorable one. The ulceration, which was probably specific, half encircled the right leg of a middle-aged woman, rather stout, and suffering in addition from chronic eczema and heart disease; the ulceration had been treated for a considerable period in the ordinary manner, but without success. Under the new treatment the ulcerating surface looked clean, the granulations were healthy, and Dr. Stoker hopes soon to see it entirely healed.

Drunkenness in Russia.—The Governor of St. Petersburg is aroused upon the increasing prevalence of drunkenness in that city, and has just ordered that the names and addresses of all persons found intoxicated in the streets, regardless of rank or sex, shall be posted in certain public places in the city and also printed in the *Official Gazette*. Fifty years ago they were compelled to sweep the streets for a number of hours, under the eye of the police.

Wants to Study Medicine.—The following letter was placed in the hands of the *Atlanta Medical and Surgical Journal* recently. The applicant is too late. The time has now passed when doctors will be made of such material:

"Dr. ——— dane Sir please send us a Catlog of the ——— College We hav bin Contemplating entring College this fall Some Wheare and if you Will give us as short a time as We Can get eny Whear and as Cheep pobly we Will enter yoars College but if We Can dow Beter Some Whea els We Will do so We air pooar in this worlds goods We think yoar tearms air tow Meny for us as we air a geting up in years We Caint spend so mutch time.

"adress ———."

Reasons Why the Abdominal Bandage Should not be Used After Labor.—1. It is unnatural. 2. It is liable to become soiled and hence a harbor for microbes. 3. It increases irritation of the tired and overworked abdominal organs. 4. It interferes with the necessity of frequent antiseptic ablutions. 5. It is difficult to keep in place, unless made to order. 6. It binds down the weak uterus and promotes the return of a displacement or a subinvolution. 7. It predisposes to puerperal and cerebro-spinal centres. 8. It increases rather than diminishes the danger of post-partum hemorrhage. 9. It prevents digestion, assimilation, and intestinal peristalsis and tends to bladder trouble. 10. It is unsafe to apply it by any one except the accoucheur or an experienced nurse.—*Southern Medical Record.*

The Serum Treatment of Diphtheria is to be tested on a large scale in France, the budget committee of the Chamber of Deputies having resolved upon an appropriation of $20,000 with which to test the efficacy of the new remedy.

The Berlin Police and Quack Medicines.—The Berlin police have adopted a neat way of stopping the sale of poisonous preparations without proceeding against the advertisers with the machinery of the law. They insert in each newspaper an advertisement to the effect that they have caused an analysis to be made, and that the article advertised is composed of so-and-so, and its intrinsic value is so much. A case in point was a cosmetic for the complexion (the composition of which we have already exposed in these columns), costing one halfpenny and retailing at half a guinea. The police, it appears, do not interfere in the case of preparations into which poison does not enter. They leave the buyer to his own resources.

A Sanitary Coffin is a term with a curious sound, for most people think they are rid of hygeia after death. An Englishman, however, has patented a sanitary coffin, which really seems to have merits. The interior of the coffin, including the lid, is lined with a 3-inch cushion stuffed with caustic and antiseptic powder. When the body is fastened in the coffin it is tightly packed in an air-tight padding, which not only absorbs and neutralizes all the products of decomposition, but also eventually destroys the tissues themselves. It would be an obvious advantage to enclose the body of any person who had previously died of an infectious disease in a receptacle of this kind, especially in view of the almost universal practice of allowing the bodies of the dead to remain for several days in the houses of the living.

Anatomical Mnemonics.—In the *International Medical Magazine* for November Dr. Henry W. Cattell, of Pennsylvania, discusses this subject in a paper which will be read with interest by students and those engaged in anatomical teaching. In the first place he quotes the well-known but nonsensical lines—

"On old Olympian's piney top,
A fat-armed girl prepares a hop."

This, it may be explained, refers to the cranial nerves. "On equals olfactory; Old, optic; Olympian's, ocular motor; Piney, pathetic; Top, trigeminal; A, abducent; Fat, facial, and so forth." The "tip" for the structures passing over the inner ankle he gives as "Timothy doth vex all very nervous people;" but the one most commonly in use for the same purpose in his country is: "The four virgins at Vei never felt love's power." Again, the situation of the valves of the heart, he says, may be readily remembered by the following words: Martin Luther, The Reformer; the mitral, of course, being on the *l*eft side and the tricuspid on the *r*ight. To give on more "tip," the word "same" comes in useful for remembering the power possessed by the spinal nerves—the Sensory nerves being the *a*fferent, while the *m*otor are the *e*fferent. We quite agree with the author that the literature upon this subject is meagre, and in view of the fact that the utility of such aids as here referred to is unquestionable, it would be only wise that the future editions of text-books on anatomy should contain some allusion to them.

The Buecilingual Fragment.—For many years it has appeared to the general public that this institution, founded by a man like Ezra Cornell and largely saved by a man like Henry W. Sage, has been conducted by and in the interests of a gigantic sporting fraternity, comprising about one-fourth of all the students. Among them are good men and earnest scholars. Among them also are evidently some who accept the doctrine recently enunciated by the President of Princeton: "I appreciate scholarship as much as anyone, but realize the fact that all of those who go to college do not desire to become fine scholars." From their ostensible vocation, study, they find time for numerous avocations, more or less laudable in themselves, but seldom conducive to scholarship. They are preeminently the patrons of inter-collegiate athletics, not

so much by playing themselves as by attending games and, until perhaps very recently, betting upon the results. They commonly have plenty of money, not often self-acquired. They contribute liberally to athletic funds; they also, however, demand that others should do the same. They clamor for aid from the antipathetic in paying the salary of a professional trainer, and in the same term spend what would pay that salary many times over for the luxury of witnessing games in distant cities. They convert the college papers into sporting gazettes. They claim to represent the institution before the public. They assume to constitute the "student body," whereas they are merely a buccilingual fragment thereof.—PROFESSOR B. G. WILDER, of Cornell University.

There is a Movement on foot to present a testimonial to Dr. John S. Billings, on the occasion of the completion of the Index Catalogue of the Library of the Surgeon-General's Office, United States Army. Dr. Billings has been most unremitting in this work, and it is considered all the world over as the most complete and valuable reference work of its kind in any language.—*Maryland Medical Journal.*

A Story of a Halfpenny.—The story in "Pickwick" of the boy who swallowed a bead necklace and rattled audibly, even when wrapped in a watchman's coat, is fairly equalled by an account that has just reached us of another boy, who swallowed a halfpenny eighteen months ago. In spite of diligent search no trace of the coin could be found, and the boy himself gave no indication of having withdrawn a coin of the realm from circulation. He remained in good health, we are told, until a few days ago, when he had an attack of pneumonia, and during a fit of vomiting the coin reappeared. If the boy had not suffered in the interval, the coin had; it was "very green," and the "engraving and date were very much worn." This is unfortunate, as it leaves an element of uncertainty in the case.—*The Lancet.*

The Power of Insurance Companies Over the Bodies of Policy-holders.—Whether insurance companies have the right to order post-mortem examinations of the bodies of the insured is considered at length in a decision of the Superior Court, General Term, as the result of which the court gives a new trial in the action brought by Charles Wehle, as executor of Lawyer Henry Wehle, to recover $10,000 from the United States Accident Association on a policy for that amount on the life of Henry Wehle, who was found drowned at Rockaway, on September 4, 1893. When the case came to trial it was dismissed on proof that a demand of the insurance company to make an examination of the body after the burial had been denied by the representatives of Mr. Wehle. The court decides that the insurance companies have no right to demand exhumation unless the contract calls for such examination in unequivocal terms.

Vital Statistics of New York City for 1894 show the lowest death-rate for eighty years, viz.: 21.05 per 1,000. This is calculated on an estimated population of 1,957,452, and compares with recent years as follows:

1888	25.23	1891	24.73
1889	24.07	1892	24.25
1890	23.51	1893	23.52

The grip epidemic accounts for the increase in 1891 and 1892. The improvement in sanitary conditions and in sanitation has been regular and steady. Here are some other comparative statistics of the year:

	1894.	1893.
Deaths	41,212	44,480
Births	55,643	51,529
Still-births	3,571	3,045
Marriages	17,388	16,144
Deaths in tenements	26,149	28,373

Hospital Sunday and Hospital Extension.—Last Sunday was "Hospital Sunday," it and the preceding day being devoted to collections for all the city hospitals—except the Presbyterian. The Hospital Saturday and Sunday Association has prepared some facts and figures relative to the hospitals of the city, covering the period 1884–94, a period in which the association has done its best work. Ten years ago three-fourths of all hospital care was provided by the municipality out of the general tax levy, and charity hospital work was thought to be possible only through endowments obtained through testamentary bequests. The association prides itself on having since then brought about a reversal from this dependence on "the duty of the dead," changing the preponderance of support to the shoulders of the living. The following comparisons will show some of the results:

	Beds in 1884.	Beds in 1894.
General hospitals	1,625	2,711
For women and children	556	1,035
For the eye, ear, and throat	152	207
For skin and cancer	30	190
For convalescents	20	119
For consumptives and incurables	170	1,010
Totals	2,553	5,272

	Total expenses.	From city.	From invested funds.	From paying patients.	From all other sources.
1884	$947,404	$181,674	$295,000	$196,103	$274,035
1894	1,840,393	151,102	481,504	366,956	840,831

An interesting fact, showing the interest of all classes of people in hospitals, is the establishment in this city, within recent years, of a hospital by the Polish and Russian Jews, and two Italian hospitals by residents from that nation. This beginning toward self-helpfulness and departure of indifference on the part of these people the association regards as especially gratifying.

Grave Robberies in Indianapolis.—The papers state that parties in search of a body stolen from Greenwood Cemetery, near Indianapolis, traced it to an unoccupied house which is being fitted up for the Indiana Medical College, and in the cellar they found twenty or more bodies. They had been brought in from country cemeteries within two or three days. The Indiana Medical College was burned several months ago, and the bodies were being collected preparatory to opening the institution in the new quarters.

Professor B. J. Alexander, of Cottner University, and D. L. Mehan and J. A. Burford, were recently held for trial in Lincoln, Neb., on a charge of grave robbery.

Library Books and Infectious Disease.—The conveyance of infection by means of books is so obvious a possibility that the greatest care should be taken to prevent its occurrence. This matter has lately been discussed in Edinburgh, where we learn a rule is in operation with the object of minimizing the danger alluded to. Rule IV., of the Free Library by-laws, provides for the cancelling of reader's tickets in case of infectious disease. Every day the library authorities receive from the medical officer of health a return of cases of infection, and steps are taken at once to ascertain if books from the library are in those houses. Books from infected houses are removed by the officers of the Public Health Department, and properly disinfected or destroyed. Whenever any book has been in a house infected by small-pox, it has been burnt on its return to the library.—*British Medical Journal.*

A Woman on Bicycle-riding for Women.—At the meeting of the Société de Médecine Publique, Mme. Gaches-Sarrante read a paper on the utility of the bicycle for women. For the last three years she has been practising this masculine exercise to the great benefit of her health. Alluding to the costume to be adopted, she insisted on the fatigue produced by the corset; the least up-hill provokes oppression from the stricture of

the thorax. As regards the genital organs, all acute inflammation should forbid the use of the machine, but where the lesions were chronic, moderate exercise might be permitted, and even enjoined; in any case, riding is much less fatiguing than standing or walking. Salpingitis or chronic salpingo-ovaritis do not constitute a counter-indication, and in cases of chronic peri-uterine inflammation the bicyclette can replace with advantage the Swedish method of massage. Bicycling exercises, consequently, a healthy influence on the physical nature of women; they sleep better, digest better, and their chest expands so as to find it necessary after a short time to enlarge the corsage of their robes. Mme. Sarrante concluded by drawing a vivid picture of the moral *rôle* of the bicyclette, the only physical exercise that husband and wife can take together.

Death in the Discharge of Duty.—We lately recorded the death of another member of the medical profession in practice near this city, which was due to an infectious disease caught from a patient upon whom he was in attendance. We have recently spoken of the constant recurrence of such examples of professional self-sacrifice, and of the large number of them every year. A foreign writer now in this country groans over his discovery that "very few Americans have any ideal in life." But there are certainly a good many American doctors who have a high ideal of duty.—*The Sun.*

Anti-vivisectionists do not Hunt or Fish.—Every anti-vivisectionist condemns the sports mentioned (hunting and fishing) and is working against them; and every well-informed person knows that both continents abound in vivisectional laboratories, in colleges, universities, and schools of all descriptions where the most awful experiments are conducted without anæsthetics, upon live animals—according to the published records of the vivisectors.—*Anti-vivisection.*

A Medical Examining Board for Georgia.—All things point at present toward the passage of a bill before the legislative body now in session, providing for a Board of Examiners for this State. The bill as now offered provides for three boards, one each for the different systems of medicine. While the editor cannot appreciate the necessity for more than one board, with representatives from the homœopathic and eclectic schools in addition to the regular schools, still if this is the only means whereby such legislation can be procured, then it is better to have this and keep its standard high than to be without any protection whatever from quacks and charlatans. We trust the factions which contended so vigorously against the previous bill are united on this one, and will push forward its passage as speedily as possible.—*Atlanta Clinic.*

New Remedies.—Among the new remedies announced in the *Therapeut. Bl.*, the first named is neurodine, acetyl-p-oxyphenylurethan, a colorless and odorless crystal, scarcely soluble in cold, but readily so in boiling, water. According to the investigations of V. Mering neurodine possesses no toxic properties, but it is an antipyretic. After 0.5 grain neurodine per dose per day, the temperature sank 2.5° to 3°C. gradually, often with free perspiration. The lowest point was reached in from three to four hours; the temperature then gradually rose. Neither cyanosis, vomiting, nor symptoms of collapse were observed after its use. As an antineuralgic it may be used with success in doses of from 1 gm. to 1½ gm. Thermodine, acetyl-p-æthoxyphenylurethan comes next in the list, also an odorless crystal, with difficulty soluble in cold water, and only slightly soluble in hot. According to V. Mering it is an excellent antipyretic. With doses of 0.5 of thermodine the temperature sank 2.5° to 3° C. It was found serviceable in influenza, the temperature fell, the headache and pains in the limbs disappeared. Generally speaking, the dose is 0.5 to 0.7 gm. It also possesses antineuralgic properties, but in this respect is inferior to neurodine. Lycetol, dimethylpiperazine is a third. According to Wiltzack we possess in lycetol a tolerably inexpensive remedy, that appears to be at least as useful in the treatment of the uric acid diathesis as piperazine. After the employment of lycetol Wiltzack observed: 1. A considerable increase of diuresis with diminished specific gravity of the urine. 2. The medicine was well borne without any disturbance of the general system, even when its use was continued for a lengthened period. 3. Cessation of the symptoms in gout, non-occurrence of an otherwise regularly recurring typical gouty attack, and considerable diminution of gravel when the medicine was persevered with.

The Southern Illinois Medical Association held its twentieth semi-annual session at Du Quoin, Ill., Thursday and Friday, November 15 and 16, 1894.

Work of the United States Bureau of Animal Industry.—The scientific inquiries of the Bureau of Animal Industry have progressed steadily during the year. Much tuberculin and mallein have been furnished to State authorities for use in the agricultural colleges and experiment stations for the treatment of tuberculosis and glanders. Quite recently this department has published the results of its investigations of bovine tuberculosis, and its researches will be vigorously continued. Certain herds in the District of Columbia will be thoroughly inspected, and will probably supply adequate scope for the department to intelligently prosecute its scientific work and furnish sufficient material for purposes of illustration, description, and definition. The sterilization of milk suspected of containing the bacilli of tuberculosis has been during the year very thoroughly explained in a leaflet by Dr. D. E. Salmon, the chief of the bureau, and given general circulation throughout the country.—*President's Message.*

BOOKS RECEIVED.

The Uric Acid Diathesis, Gout, Sand and Gravel. By Dr. F. Levison. 12mo. Price, 3*s.* 6*d.* 152 pages. Published by Cassell & Co., Ltd., London.

Manual of Practical Morbid Anatomy. By Drs. H. D. Rolleston and A. A. Kanthack. 12mo, 240 pages. Price, $1.60. Published by Macmillan & Co., New York.

Essentials of Homœopathic Therapeutics; Being a Quiz Compend, etc. By Dr. W. A. Dewey. 8vo, 266 pages. Price, $1.58. Published by Boericke & Tafel.

The Dynamics of Life. By Dr. W. R. Gowers. 12mo, 70 pages. Price, 75 cents. Published by P. Blakiston, Son & Co., Philadelphia, Pa.

Syllabus of Gynecology. By Dr. J. W. Long. 12mo, 133 pages. Price, $1.00. Published by W. B. Saunders, Philadelphia, Pa.

Notes on the Newer Remedies. By Dr. David Crena. 8vo, 253 pages. Price, $1.25. Published by W. B. Saunders, Philadelphia, Pa.

Helps in Sickness and to Health. By Henry C. Burdett. 8vo, 471 pages. Illustrated. Price, 5*s.* Published by The Scientific Press, Ltd., London.

Hypnotism: How it is Done; Its Uses and Dangers. By Dr. James R. Cocke. 8vo, 373 pages. Published by the Arena Publishing Co., Boston, Mass.

Blood Serum Therapy and Antitoxines. By Dr. George E. Kreiger. 8vo, 69 pages. Illustrated. Published by E. H. Colegrove & Co., Chicago, Ill.

NEPHROPTOSIS: ITS CAUSATION, TREATMENT, AND ITS RELATION TO MANY OBSCURE SYMPTOMS IN WOMEN, WITH REPORT OF SEVENTEEN CASES.

BY WILLIAM W. STEWART, M.D.,

COLUMBUS, GA.

THESE cases are far more frequently met with in the routine work, not only of the gynecologist, but in the daily calls of the general practitioner, than many suppose.

Lindner, of Germany, in his work "Anatomy, Etiology, and Diagnosis of Floating Kidney," states emphatically, after a large number of examinations of women from all classes, that every fifth or sixth woman has movable or floating kidney well developed.

Edebohls, in a paper read before the New York Academy of Medicine, states that one in every six women consulting a gynecologist suffers with nephroptosis.

Dr. Mathieu, in a paper read before the Société Médicale des Hôpitaux, stated that he examined three hundred and six women who were admitted into the hospital for other complaints, and found the condition known as movable kidney in forty-five. He also examined forty-six women suffering from severe dyspepsia, and found the kidney abnormally movable in thirty-two. He tabulates upon the results of his examinations as follows: "Nephroptosis is found in patients between fifteen and twenty years, in from twelve to thirteen per cent. Between twenty and twenty-five, in from twenty-two to twenty-three per cent.; between twenty-five and fifty years of age, forty per cent.; and between fifty and seventy-five years, twenty-five per cent."

In women who have not borne children the condition was far less frequent than in those who had; thus, in one hundred and four multiparæ it was found only in $\frac{54}{104}$ per cent., while in those who had borne one or more children the percentage rose to $33\frac{80}{100}$.

This condition is one peculiar to women, as shown by the following figures:

Roberts states that out of 70 cases coming under his observation, 61 occurred in women and 9 in men. Ebstein, that of 96 cases, 82 were females, 14 males. Dickinson, that out of 12 cases, 10 females, 2 men.

This condition may be congenital or acquired, but is usually acquired, appearing in the child-bearing period. The congenital form is the result of a malposition or formation of the peritoneum; in these instances the kidney is often completely surrounded by peritoneum which forms a pedicle, with ureter blood-vessels and nerves, the kidney having a complete mesonephron. When the condition is congenital, it usually appears as a floating kidney, and is often associated with malformations. Of this variety, it can truly be said that the kidney can be found in all portions of the abdominal cavity, often shifting its place.

The acquired is most commonly detected after childbirth, and especially in those women whom one often meets and in whom there is a general relaxed condition of the muscular system, who most frequently have uterine and other associated visceral displacements.

As to the causation of the acquired forms, childbirth stands first. After this come tight lacing, falls, acute inflammatory conditions of the kidney, which increase its size, thereby distending its peritoneal covering, followed by rapid shrinkage of the organ, thus leaving the kidney a free space in which it may move, by its mobility gradually enlarging the sac thus formed. Acute hydronephrosis caused by stone or gravel slowly passing through the ureter, produced by the rapid enlargement and quick shrinkage of the kidney by which it is loosened from its attachments. Rapid absorption of the fat surrounding the kidney as is produced by wasting diseases, quite often leaving unoccupied space allowing marked mobility. Lifting of heavy weights, by which the liver is forced downward and presses upon right kidney; especially is this prone to occur when a tight corset is worn.

The right kidney is much oftener displaced than the left. Of 91 cases reported by Ebstein, the right kidney was affected in 65, the left in 14, and both in 12.

Tuffin, in an article published in *La Semaine Médicale*, Paris, September 16, 1892, very aptly classifies this condition clinically into three forms; viz., the painful, the dyspeptic, and neurasthenic. This classification, though good, can rarely be found distinctly exemplified, as each case presents more or less the symptoms of all. But, yet one of these usually predominates and thus gives the truest and most convenient form of distinctive classification under which the symptoms can most clearly be portrayed.

Painful Nephroptosis.—Patient usually complains of inability to walk or ride long distances on account of severe aching pain in back and abdomen, often associated with dragging and a feeling as if a body were shifting in position on change of posture. Pain is also invariably referred to bladder, urethra, labia majora, and inner side of thigh to knee; pain in bladder and urethra at times so constant and severe, and associated with frequent micturition, that one might be led to believe the existence of a urethritis and cystitis, did not the urine on examination prove normal in every respect. Pain is often complained of in finger- and wrist-joints, and an almost constant pain in top of head similar to that experienced by patients suffering with metritis. All these symptoms are much increased in severity during menstrual period and under excitement. There may be added to this acute attacks of renal pain, caused in some instances by acute hydronephrosis, and in others by a twisting of the pedicle, formed as it is by nerves and blood-vessels—the twisting causing a direct infringement upon the nerve-trunks; or, an acute congestion brought about by an obliteration of the flaccid walls of the veins, while the stiff and patulous arteries continue to flood and swell the kidney with blood.

Dyspeptic Nephroptosis.—A patient thus affected usually presents a forlorn picture of chronic dyspepsia with marked tendencies to melancholia. Stomach and duodenum usually dilated, pain more or less constantly felt over region of bowels, with frequent attacks of nausea and vomiting. Mouth frequently ulcerated, gums spongy, bleeding on slight pressure. Tongue red, sore, and at times ulcerated. Alternating attacks of constipation and diarrhœa. The extent of these symptoms, of course, largely depends upon the length of time the condition has existed and amount of obstruction produced by the dislocated kidney.

The theory of dilatation of stomach associated with

nephroptosis, was first brought forward by Bartel. He claims that in tight-lacing the kidney is often pushed down, and a descending portion of the duodenum is pressed upon thereby, thus often obstructing or making difficult the outflow of the stomach.

Glénard, on the other hand, rather considers the nephroptosis as an associated condition, and points out the prolapse of various organs as the cause of nervous dyspepsia. According to him, the hepatic flexure of the colon, the transverse colon, and the stomach sink in position. The enteroptosis thus ocurring may produce a kinking of the duodenum caused by its false relation to the stomach. The stomach contents will then with difficulty pass. With this condition he considers a nephroptosis but a continuation of the tendency to the displaced and false relation of organs.

Dr. Mathieu discussed this subject before the French Medical Society, which discussion was reported in *Le Progrès Médical*, in which paper he cited many cases in whom there had been severe attacks of vomiting, in some cases ten or twelve times a day for a fortnight or more, strongly resembling in some instances the gastric crises of locomotor ataxia. Associated with this vomiting were severe abdominal pains.

These views were endorsed and concurred in by Doctors Legendre and Rendu.

Neurasthenic Nephroptosis.—This type of cases is less marked than either of the foregoing, and is more seldom seen. The manifestations are usually in the form of profound hysteria, hypochondriasis, and melancholia, all of which symptoms are quickly benefited, and in some instances permanently relieved, by appropriate treatment.

Diagnosis.—This can usually be definitely made by carefully questioning patient as to symptoms, not only as to pain in region of kidney, but as to referred pains to other organs and regions of body which are coupled closely by direct nerve communication, or are so affected through the sympathetic. With this history and a careful physical examination made with patient on her back, with knees flexed, then by pressing backward close up underneath last rib firmly and slowly till muscular resistance is overcome, the kidney, in people who are not too fat, can be easily felt and its mobility determined.

If none be felt with patient upon back, a change of position to side, followed by deep inspiration, will usually elicit any freedom of movement that may exist.

Pressure upon such a kidney not infrequently calls forth a nauseating, sickening feeling peculiar to this condition. The feel of the kidney, when located and movable, is much like an ovary or testicle in the scrotum, in the peculiar quickness with which it slips from beneath the fingers.

Differential Diagnosis.—This condition has to be differentiated from wandering spleen ; new-growths of the mesentery ; tumors of the head of the pancreas ; tubercular conditions of omentum ; and lastly, and by far the most difficult condition requiring differentiation, diseases of the gall-bladder.

As to the differentiation between nephroptosis and all the foregoing pathological changes except the last, there can be rarely much trouble ; for the history, coupled with careful physical examination, will usually clear up all doubt that may exist. As to the last named, a differentiation between right nephroptosis with hydronephrosis and distended gall-bladder, there often arise many questionable points, I myself having had one patient having both conditions existing alternately in several successive seizures, extending over a period of three months. In such an instance it will frequently resolve itself into a question to be determined only by exploratory incision.

In many instances where gall-stones obstruct the cystic duct, giving rise to large tumors of the gall-bladder, there never at any time exist the slightest jaundice or trace of bile in the urine, as is illustrated by the histories of Cases Nos. II., III., VII., and VIII., reported and operated on by Dr. J. B. Murphy, MEDICAL RECORD, January 20, 1894, pages 72, 73, and 74.

On the other hand, jaundice can be caused by a dislocated or hydronephrotic kidney. Such a case is reported in the *British Medical Journal*, January 29, 1876. In this case jaundice was produced by the compression of the common duct by a dislocated kidney which was in contact with the transverse fissure of the liver and adherent to the duodenum. Thus it may be seen that with either condition we may or may not have jaundice. Therefore jaundice has no absolute diagnostic value.

At the time of the acute attack the tumor is usually too tender for palpation to be of much use in diagnosis. And when all soreness subsides and palpation can be used as a thorough means of investigation, all tumor may have entirely disappeared ; which is sure to be the case alike in hydronephrosis caused by occlusion of the ureter by a small stone, and in a distended gall-bladder with obstructed cystic duct. In such an instance the finding of a nephroptosis only points to the kidney as the possible seat of trouble, and does not exclude the possibility of there having been a distended gall-bladder. In both instances the acute attacks are associated with persistent nausea and a temperature variable in intensity alike in both. The sudden filling of the bladder and evacuation of a large quantity of urine, blood-stained or foul in odor, or in some instances free of all odor and cloudy in color, when associated with disappearance of pain and tumor, can be deemed conclusive evidence of right hydronephrosis.

The urine being stained with bile is, on the other hand, not distinctive of occlusion of the cystic duct *per se*, as is shown by report of case in *British Medical Journal*, January 29, 1876. In such a case the differential diagnosis can only be made out by the presence or absence of characteristic discharges of urine attended by relief, as cited above.

Treatment.—This can be divided into surgical and mechanical.

The surgical consists in stitching the kidney to the muscles of the back. The surgical procedure is too ably described in all recent surgical works and monographs on this subject, to require further mention here, and is only required in those cases where marked mobility of the kidney exists uncontrollable by a properly fitting bandage.

Mechanical Treatment.—This, by far the safest and most satisfactory treatment, consists in a carefully fitted abdominal belt made of silk elastic with perineal straps to retain it in position. It may be found necessary in some instances to use, in addition to belt, a pad of horse-hair or wool covered with kid, to be placed just below the kidney.

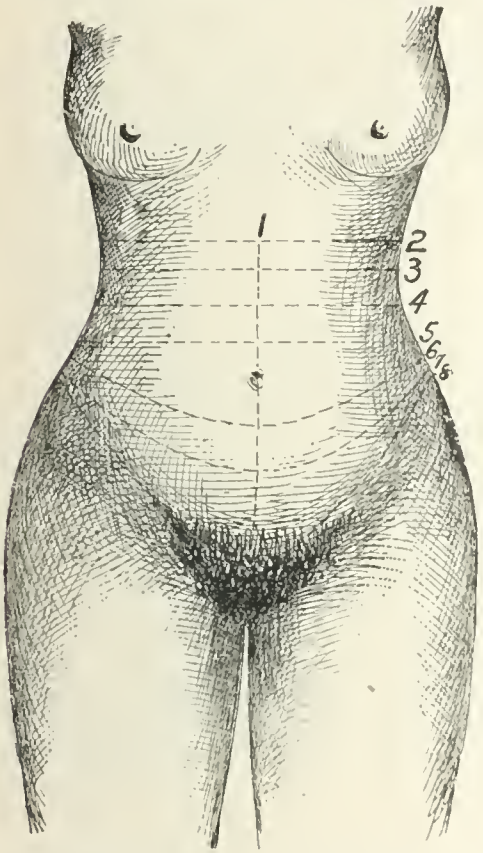
One reason for the unsatisfactory results obtained by the use of bandages, reported by some observers, I feel sure, consists in the fact that the belts are in the first instance not properly fitted.

To secure the kidney in position great care is required in taking proper measurements from which the belt shall be woven. More measurements should be taken than is usually required by manufacturers. Those measurements which have been found necessary by me to secure a perfect fit, are shown in accompanying cut. The belt should extend as high as the last rib and should be quite snug in fit. All measurements should be taken from the naked body, patient standing squarely upon both feet. Tape should be drawn almost uncomfortably tight at each point of measurement.

After trying various manufacturers, with various degrees of satisfactory results in fit and good workmanship, I have found most complete satisfaction in the work of the Pomeroy Company, 785 Broadway, New York

Report of Cases.—CASE I.—Mrs. A——, aged thirty-four, married seven years. One child born thirteen months after marriage. Labor hard. Instrumental delivery after twenty hours. Convalescence from confinement slow. Six months after began to be troubled

occasionally with attacks of biliary colic with marked jaundice. One year ago patient was sent to me for treatment involving uterus, tubes, and ovaries. Three weeks after coming under my care she was suddenly attacked with what she considered biliary colic, as the pains were the same in location and feeling as in previous attacks which had been diagnosed as biliary colic. On examination there was found an elastic tumor, painful on pressure, freely movable just beneath last rib on right side, separable from the liver. Pressure upon this tumor produced profound nausea, which would last for some hours after. No jaundice. Bowels regular. Movements normal in color. Urine scanty, highly colored, extremely acid, causing considerable excoriation and pain in passing. Temperature rose on second day to 103° F., varying between 100° F. and 103° F. for four successive days. Tumor in right side daily increased in size, becoming exquisitely painful to touch. Nausea after second day was constant. An average of two



grains of morphine in twenty-four hours was required to make pain tolerable. On fourth day patient suddenly experienced relief from pain accompanied with an urgent desire to urinate. She then voided a large quantity of dark, foul-smelling urine, freely intermingled with blood, after which temperature dropped to normal. She had been peculiarly free from pain during intervals of attack. After soreness subsided kidney could be well made out as freely movable. Bandage applied with right pad. No attacks since.

Case II.—Miss S——, aged nineteen. Had been in perfect health until one year ago, when on a visit to friends in the country, she became one of a party to enjoy a straw-ride, the vehicle being a high farm wagon without springs. When the destination was reached she thoughtlessly jumped from the side of wagon to the ground, a distance of about six feet. Immediately she experienced a sharp pain in the right side just beneath the ribs, but thought nothing of it. The acute pain soon subsided, and in its place she suffered with a heavy, aching pain associated with dragging in region of right kidney. This continued with varied intensity until time of attack. On her return home she began to jump her sister's baby, which weighed about thirty pounds. In a few weeks she began to suffer with pain in bladder and urethra, with more or less constant desire to urinate. Also an aching of labia majora, as if they were bruised, pain extending down right thigh to knee. Headaches in back of head. Shifting pains in finger- and wrist-joints. The menstrual period, which previously had been free from pain, was now associated with marked increase of all foregoing symptoms. Five months ago began to be troubled with chronic dyspepsia. No appetite. When food was taken into the stomach, after several hours parts of it would be vomited undigested. Bowels became constipated. Four months ago was seized in the right side with severe pain. At this time I was called in, and on examination found a tumor in right side below the edge of the liver, quite tender, slight pressure upon which caused several successive convulsive efforts to vomit. Temperature rose by second day to 104° F., ranging between 104° F. and 102° F., for ten days. Pain was kept under control by phenacetine and codeia. On fourth day she passed a large quantity of turbid, odorless urine, after which she was completely relieved of pain. In two days tenderness had sufficiently subsided for diagnosis of nephroptosis with acute hydronephrosis to be confirmed. Measurements were taken for a belt; but before it arrived she was taken with a second attack much lighter than the first, only lasting five days; same temperature and slight pain. Kidney, in this instance, reached only half the size as in previous attack. Belt and pad applied with perfect relief of all symptoms. Says now she feels better than ever before.

Case III.—Mrs. O——, aged forty-eight. Four children. Labor normal. Five years ago was operated upon for large fibroid of uterus, which was removed. Health ever since has been bad. Chronic dyspepsia. Locomotion painful. Constant dragging pain in back, only relieved by recumbent position. Bowels constipated. Inclined to be hysterical. Pain in bladder, urethra, and on inner side of thighs. Has been treated by various physicians for neuralgia of the bladder. Urine normal in quantity, containing albumin ten per cent. by measure. Physical examination revealed abdominal muscles extremely relaxed. Both kidneys movable: slightly enlarged and painful on pressure.

Treatment.—Patient was ordered a milk diet and rest in bed, under which albumin quickly disappeared from urine. Belt was then applied, with two pads, which completely relieved all pains in bladder and other locations. Constipation and dyspepsia soon disappeared. Patient is now well. Can walk several miles without the slightest fatigue. Has had no trace of albumin in urine for three months.

Case IV.—Mrs. B——, aged thirty-five. Seven years ago became pregnant. About the third month of pregnancy began to suffer with pain of a colicky nature at intervals of from one to three weeks. Pain was located in right side, just beneath last ribs and in back. Was never jaundiced during any of these attacks. Labor hard, with instrumental delivery. Convalescence from confinement slow. From time patient began to walk complained of backache, which was more or less severe all the while. Bowels regular. Five years ago she was seized with a severe pain in right side much more severe than any previous attack, lasting four days, and requiring morphine to make pain tolerable. Urine dark, scanty, and highly colored with bile. Fæces almost white. Marked jaundice. After this attack was quite weak. Failed to respond to restorative agents. Was then advised to travel in the West, which she did for several months with marked improvement. While on this trip had another attack associated with some jaundice. These continued to return at intervals of from two to six months for four years. Then she had no more till December, 1892, but had pain in back more or less constant. Digestion good. No vesicle or urethral symptoms. Bowels inclined to constipation. Menstruation free from pain. During the month of

December, 1892, had two quite severe attacks, during which I was called in.

When first seen she complained of severe pain located over region of liver, extending to median line, associated with nausea and vomiting. A tumor could be made out just beneath the free border of ribs on right side, hard and exquisitely tender. Tongue coated and yellow. Skin and conjunctiva slightly yellow. Urine scanty and stained with bile. Temperature 100° F. Fæces passed next morning after enema, clay colored. This attack lasting seven days, required morphine at intervals of about six hours to give patient some relief. After second day jaundice became quite marked, temperature rising to 103° F. On the sixth day, as bowels were constipated from the use of morphine, a dose of Rochelle salts was given, which in a few hours produced a free watery evacuation. Bowels moved the next morning of themselves. Two hours previous to their action patient expressed herself as much relieved of the feeling of heaviness and weight in the hypogastric region. On examination of discharges from the bowels they were found to contain a good many hard lumps of fecal matter intermingled with a considerable quantity of muco-pus and blood, which had been acted upon by intestinal juices, after which discharge temperature dropped to normal and convalescence was quite rapid, with complete disappearance of tumor.

A few months later, while in Chicago, was taken with a similar attack much lighter than the previous one. Was diagnosed by attending physician of hotel as an attack of biliary colic. In April, 1893, while out riding, the horses becoming frightened and unmanageable, she jumped from the carriage, falling upon buttocks, at which time she experienced sharp pains in pelvis and back. On her return home I was immediately summoned, and on examination found the uterus forcibly retroflexed. This condition had not existed previous to fall. Uterus was restored to place and steadied by wool tampons, with prompt relief. In May was called in to attend her in another attack. On examination there was found a large tumor in right side, exquisitely tender on pressure, which extended well up under ribs. Definite outlines could not be determined, as pain precluded thorough palpation. No jaundice. Bowels constipated. Constant nausea. Urine scanty, high-colored, and free from bile. Complained of pain in bladder, urethra, and external genitals, also in inner side of thigh to knee. Temperature ranged from 101° F. to 104° F. Morphine was constantly required to relieve pain. On sixth day an unusually large amount of clouded urine was discharged, which was quickly followed with relief. This case is one peculiarly instructive as demonstrative of the existence in the same person of two conditions so strangely similar in their manifestations, but yet so dissimilar in the causative lesion and appropriate treatment.

My diagnosis in all attacks except the last was biliary colic, with ulceration through into the duodenum during one attack. Feeling uncertain as to my ground as to the last, and wishing for advice as to the advisability of operative procedure upon the gall-bladder, and not feeling that the movable kidney took much part in her sufferings, I sent her to Dr. E. G. Janeway, of New York, who saw her for me and advised the use of abdominal belt, feeling that the kidney was largely to blame for her sufferings, and that no surgical procedure should be attempted upon gall-bladder, as he could find no evidence of disease or obstruction at time of examination. Since the wearing of belt patient has been free of all pain and greatly improved in health. It is quite probable that the associated nephroptosis was brought about by the fall received in April, 1893.

Case V.—Mrs. B——, aged forty-seven. Has had seven children. Since the birth of the third has been an invalid, from vesicle and urethral pains and dragging sensation in back, associated with chronic dyspepsia; these symptoms were persistent during the intervals between pregnancies and up to the third month of pregnancy, at which time all troublesome symptoms would gradually disappear, only to immediately reappear after confinement. Two years ago she was sent to me for treatment and repair of perineum and cervix. On careful examination left kidney was found displaced to a considerable extent, right kidney slightly so. Patient having a severe endometritis, she was curetted and cervix and perineum repaired. After recovery from these operations a belt with two pads was applied, which resulted in her complete restoration to health. It is an interesting fact to note in this case that the uterus, as it enlarged and rose in the abdominal cavity, so increased the intra-abdominal pressure that all displaced viscera were pushed back into position and held there, thus relieving the painful symptoms, which would reappear on the uterus returning to its unimpregnated state.

Case VI.—Mrs. S——, aged thirty. One child. Has been married eight years. Since birth of child six years ago, patient has been an invalid suffering with pains in back, head, thighs, bladder, and urethra, with recurring attacks of colicky pain of more or less severity in right side never associated with jaundice. Has also been a great sufferer from chronic dyspepsia. Bandage and pads applied with relief from all distressing symptoms.

Case VII.—R——, infant, eight months. Swallowed some pieces of plaster while nurse was inattentive, which was followed by intestinal obstruction. All medical treatment having failed after thirty-six hours' effort, the attending physician decided the case was one demanding immediate surgical attention. I was asked to operate. On examination, though abdomen was quite tympanitic, a distinct tumor could be felt on right side half-way between crest of ilium and umbilicus. Tumor was movable. Its exact consistency and shape could not be made out on account of tympanitic condition of abdomen. All who were present agreed in the belief that this tumor was the obstructed gut, probably of volvulus. The mother was questioned carefully, but stated that she had never noticed the abdominal tumor previous to this time, which she could now feel with the greatest ease. Child being placed under chloroform, median incision was made and fingers passed into abdominal cavity. The tumor was found to be a floating kidney; the obstruction being an intussusception located in left hypogastric region. This I believe is the youngest case of floating kidney yet reported. The child had never suffered any inconvenience from this deformity.

Case VIII.—Mrs. S——, aged twenty-six. One child five years ago, since which time has been a constant sufferer from dyspepsia, never having suffered previously; also from acute attack of sharp, lancinating pains with intense fulness, which come on at intervals of from three to four months. These attacks had been looked upon as the result of acute indigestion. Eight months ago she first came under my observation. On careful investigation right kidney was found freely movable. Belt and pad were applied with thorough and prompt relief. Three months after first seeing her she became pregnant. After third month she was enabled to leave off belt with perfect comfort, as the enlarged uterus held the kidney in position.

Case IX.—Mrs. R——, aged fifty-one. Has had four children. Health till one year ago was perfect. At that time her eldest son, a large man weighing about one hundred and sixty pounds, was taken sick with typhoid fever. She nursed him through his illness, often lifting him from one side of the bed to the other. Gradually she developed a dead aching pain in right side and back just beneath the free border of ribs, which she described as feeling like a constant tooth-

ache. This continued to increase in severity till it culminated in an acute attack, which occurred about two months after his recovery. During the night she was seized with sharp, lancinating pains in right side, so severe that before her family physician, who was immediately summoned, could arrive, she was almost in collapse. She complained also of great pressure and fulness just beneath the last ribs. Temperature quickly rose to 103° F., where it remained with slight variations for six or eight days. On the sixth day after acute attack I saw patient in consultation. At that time there was a considerable localized peritonitis, and a large tumor could be made out below the liver and extending to crest of ilium. Diagnosis arrived at was acute hydronephrosis following nephroptosis, the latter being brought about by the lifting of her son during his illness. The later history of this case I am unable to give, as she passed from under my observation.

Case X.—Mrs. C——, aged twenty-two. One year ago was delivered of a large child. Labor slow and hard. Recovery from confinement good. Previous to confinement was in perfect health. After resuming her household duties began to suffer with dragging pain in left side, and recurring attacks of acute pain located just beneath the free border of ribs on left side. Pain was experienced also in bladder, urethra, labia majora, and thigh. During acute attacks was always much nauseated, which persisted till pain subsided. Has never suffered from dyspeptic symptoms. On examination left kidney was found movable. Belt and pad applied with relief.

Case XI.—Mrs. C——, aged twenty. One year after marriage was confined. Labor normal. Since which has been a great sufferer from backache. No other symptoms. On examination both kidneys found movable. Bandage applied with complete relief.

Case XII.—Miss I——, aged sixteen. Quite fleshy, which fact was a distinct source of embarrassment to her. To avoid this appearance to some extent she laced very tightly. As a result, right kidney was dislocated, associated with recurring attacks of hydronephrosis, with all characteristic genital pains, all of which were much aggravated at menstrual period. No dyspepsia. Bandage and pad applied with satisfactory results.

Five other cases with the usual train of symptoms are now under treatment, or have recently been seen. As sufficient time has not elapsed to give definite results as to treatment, no further mention will be made of them in this paper.

Acetanilide for Vomiting.—Among the many uses to which acetanilide has been put, other than that of an analgesic, we desire to call attention to its employment in the treatment of obstinate vomiting, particularly when that vomiting seems to be due chiefly to nervous disturbance or marked gastric irritability. In the treatment of the vomiting following operations, acetanilide is particularly useful, and the administration of two grains every hour until six grains are taken, will often prevent this unpleasant sequel of operative interference. We have used acetanilide for this purpose a number of times with very satisfactory results, our attention having first been called to it by Dr. Brown, of Sioux Falls, S. D., who told us that it was his custom in country practice to leave acetanilide with the nurse after the operation, with instructions to administer the drug should vomiting after recovery from the anæsthetic be an annoying symptom.—*Therapeutic Gazette.*

The Number of Medical Students and the out-put of medical graduates has greatly decreased in Ireland in the last few years. In England and Scotland there has been a great decrease in the number of medical students. The cause is said to be the addition of a fifth year and of extra studies to the curriculum.

AN EPIDEMIC OF TYPHOID FEVER AT BAYHEAD, N. J., FROM DIRECT INFECTION OF A MILK-SUPPLY.[1]

By W. H. KATZENBACH, M.D.,

NEW YORK.

Bayhead is situated in Ocean Co., N. J., midway between New York and Philadelphia. It occupies a strip of land between the Atlantic Ocean and the head of Barnegat Bay. The Pennsylvania Railroad runs along the western border of this strip, and separates for the most part the summer residents on the east from the native or permanent residents scattered among the pines on the west. Bayhead includes ninety to one hundred cottages, three hotels, and two boarding-houses. The population during the summer is estimated at about twelve hundred.

Bayhead is supplied with water from two artesian wells, one over seven hundred feet deep, and the other over nine hundred feet deep, and yielding about seventy gallons per minute. The water is pumped into an elevated wooden tank of ten thousand gallons capacity, whence it delivers itself through pipes to the several houses.

Previous to the introduction of the artesian water in 1886, the earth-closet system was in vogue for the disposal of the soil, and small cesspools were used to receive the kitchen drainage. Since that date water-closets have been introduced into the new cottages, and also into many of the older. All the drainage of these houses goes into cesspools. The sanitary condition of Bayhead has always been excellent. During July of the present year a small epidemic of typhoid fever, which included fifteen cases, appeared in the borough.

The first case was Fred J——, twenty-one years of age, who came about the middle of June, from Whitesville, fifteen miles distant, with a herd of eight to ten cows. These he stalled and pastured on a small farm belonging to Mr. H——, situated about one-half mile from the railroad station. He boarded with the family of Mr. D——, who lived about one hundred yards from Mr. H——. When he arrived, Fred was not feeling well, complaining principally of constipation, for the relief of which he was obliged to take cathartics. I saw him professionally on July 13th, when I learned that he had been suffering since July 1st with severe headache, constipation, and abdominal pains. He had had three attacks of nose-bleed. He had milked the cows daily until July 11th, when, unable to be about any longer, he took to bed. At the time of my visit, in the evening, his temperature was 102.5° F.; his spleen was enlarged; his abdomen was tender, particularly in the right iliac region, and there were several rose spots on his abdomen. His mind was clear. He was under the care of Dr. Tunis, of Manasquan, and I was called on account of Dr. Tunis's inability to visit him that day. On the following day, July 14th, he was removed to his home, and, I subsequently learned, went through several weeks of typhoid fever, but made a good recovery. A short time after his return his sister was attacked with the same disease at Whitesville, was very ill, and recovered.

On the evening of July 14th, Kate C——, aged twenty, a waitress, who had been in Bayhead one month, consulted me at my office. She had had headache, fever, loss of appetite, and constipation for five days. Physical examination was negative. Her temperature was 101.8° F. She was given a laxative and capsules of quinine and phenacetine. On the following afternoon her temperature was 102.8° F., her bowels had acted freely, her headache had diminished.

July 16th, A.M., her temperature was 101.8° F.; P.M., 103.6° F. Examination of abdomen was negative. Her ailment, however, being suspected as typhoid, she was taken to Philadelphia on the morning of July 17th. She entered hospital, and went through

[1] Reported to the New York Clinical Society, October, 1894.

typhoid fever complicated with abscesses, one under the chin, and one on each buttock.

July 16th.—I was called to see James N——, aged eleven, who had been in Bayhead three weeks. He had begun to complain the day previous of severe frontal headache and fever, and was constipated. At my first visit, in the evening, his temperature was 100.5° F., and his spleen was enlarged. The fever pursued the course of typhoid.

July 20th.—He had a slight nose-bleed, and rose spots on the abdomen.

July 22d, the eighth day of his illness, his condition being favorable, he was removed to his home in West Hoboken. The duration of his fever was thirty-one days, and uncomplicated.

On the morning of July 18th, I was consulted by Miss C——, aged twenty-six, resident of Bayhead three weeks, on account of severe headache. Her pulse was 72, and temperature 98.4° F. She had a chill early the next morning, and when seen by me in the evening (July 19th), her pulse was 92, and temperature 100.2° F. Her spleen was enlarged, but there were no other abdominal signs.

July 20th.—Chill at 3.30 A.M., temperature, 100.1° F.; 12 M., temperature, 103° F.; 9 P.M., temperature, 104° F.

July 21st.—Chill at 3 A.M., temperature, 100.1° F.; 9.30 A.M., temperature, 104° F. She complained of severe occipital headache; there was no rigidity; intellect clear. She had been given quinine and was thoroughly cinchonized. Rose spots appeared July 25th. Her fever continued twenty-three days, without complication.

July 17th.—A young lady, aged twenty-five, came under the care of Dr. B. F. Hawley, with typhoid fever.

July 20th.—Dr. D. J. Milton Miller had two cases, one a girl aged twelve, and the other a female servant aged twenty-two.

Regarding the contamination of the artesian water as improbable (an examination shortly after showed the water pure), and knowing of the first case, Fred J——, on the milk farm, it was at once suspected that these subsequent cases were infected from him, as all had been drinking milk served by the dealer who bought Fred's supply. This dealer, Mr. C——, owned no cows, but purchased his milk from three dairies, and from the Milk Dealers' Association of Camden. He supplied forty-eight families in Bayhead, and a large number in Point Pleasant, one mile and a half distant, where he resided. Two other dealers distributed milk in Bayhead, Mr. J——, who had two cows, and Mr. T——, who owned and managed a dairy-farm at Allaire, eight miles from Bayhead. No cases appeared in the cottages and hotels receiving their milk from these sources. In Bayhead Mr. C—— sold only the Camden milk and Fred J——'s. All his cans were cleansed with water from his own well, and taken to the farms, where, without further cleansing, they were filled.

In the absence of a local board of health, the New Jersey State Board was notified July 23d of the presence of typhoid fever, and was requested to send a representative to take action in the matter. In this communication no hint was given that milk was suspected of being the cause of the epidemic.

Mr. George W. McGuire, the State Dairy and Food Commissioner, arrived July 25th, and after investigating, took samples of milk from Fred J——'s remaining cows, and water from the wells on all the farms from which Mr. C—— purchased milk.

July 27th.—Dr. A. Clark Hunt, member of the State Health Board, visited Bayhead, and with Dr. Miller and the writer, inspected the cottages where cases of the fever were occurring. He examined the plumbing, drains, and cesspools, and was satisfied that nothing in their condition would account for the outbreak of typhoid, and that the milk sold by Mr. C—— was responsible. The sale of Fred J——'s milk had been stopped July 22d, and seven of his cows were taken back to Whitesville July 24th or 25th. At this latter date only four families were receiving milk from Mr. C——. On July 28th Mr. C—— was prohibited by Mr. McGuire from selling milk any further in the borough.

From July 23d to 30th, eight more cases occurred, including the driver of Mr. C——'s wagon, who was attended by Dr. Whittaker, of Point Pleasant. Although one of these was taken ill in Philadelphia, it properly belongs in our list. It was that of a female servant who had been drinking Mr. C——'s milk. July 2d she was attended by Dr. Miller for some slight ailment and returned to her home on that date. On July 17th she was taken ill with typhoid fever. These make a total of fifteen cases, all of whom consumed milk supplied by Mr. C——. Four were males, eleven were females; six of the latter were domestic servants. Four patients were under fifteen years of age. The youngest was a boy aged four and a half years, the oldest, a female servant aged thirty-five. All recovered. The writer visited professionally nine of these patients. Seven of them were sent to their homes and reports were received concerning them from time to time until their convalescence. The remaining two were young ladies aged respectively twenty-one and twenty-six. The duration of the fever in the first was twenty-one days, and in the other twenty-three days. One was a severe case, with temperature of 105° F. to 105½° F. the first ten days. Neither of the patients had any complications. Of the 15 cases, 3 had one relapse each. As far as I could learn, none had intestinal hemorrhage. One case was complicated in her relapse by thrombosis of the leg, and one had an abscess under the chin and on each buttock.

From the above facts it is certain that these patients were infected by milk, and that from Fred J——'s can. He showed his first symptoms July 1st. From this date until July 11th, when he took to his bed, he milked the cows daily. The first case of the fever appeared in Bayhead July 14th, just two weeks after his first symptoms, and the last case July 30th, nineteen days after he stopped milking. His milk was never cooled and was warm when served to the cottages by Mr. C——, and none of it reached Point Pleasant. Mr. C——'s cans were cleansed with water from his own well before they were sent to the dairies, and no water was used in the cans at the dairies, except at one, for the purpose of dilution, and this watered milk was sold in Point Pleasant. Mr. C—— and his family drank the water from his own well, and none of them had typhoid fever; nor did any cases of the disease occur in any family to whom he sold milk in Point Pleasant; nor on either of the farms supplying him with this milk. There were no cases in Point Pleasant throughout the summer. Fred J——'s can was also cleansed with the Point Pleasant water after it was returned empty from Bayhead. Mr. H—— and his family at Bayhead drank from their own driven well, and no one was ill. Fred J—— boarded with Mr. D—— whose wife and four children, a son of twenty-four, two daughters of eighteen, and sixteen, respectively, and a son of fourteen, drank from their well, and none were ill during the summer. They drank milk from their own cow milked by their father. From these facts it is fairly conclusive that the milk was not infected from water used in the cans for cleansing or dilution. The only way, consequently, in which the milk could have been infected was by Fred J——'s hands. How this could occur can be left to the imagination of those who are familiar with the personal habits of some who work on dairy-farms.

If we estimate an average of eight persons in each cottage during July (when they have fewer visitors than later), about four hundred individuals would have had an opportunity of drinking Fred J——'s milk. Leaving out Fred J—— and Mr. C——'s driver, who

lived west of the railroad, we have 13 cases occurring in only ten cottages, three of the ten having 2 cases each. It is probable that some of the cottages served by Mr. C—— never received any of the infected milk, for I know of a number of young persons who drank very freely of Mr. C——'s milk without any ill effect. From the driver of the milk wagon I learned that he started out each morning with the can of Camden milk and that of Fred J——'s, which he always served separately. Beginning with one he would "run it out," and then serve from the other can. One morning he would start at the northern limit of the borough; another, at the southern limit; and it is a curious fact that there was a case in each "end" cottage, and fewer cases in the cottages centrally situated. It is probable, also, that only about two hundred persons in all drank Mr. C——'s milk; and as the number of cottages who received Fred J——'s milk cannot be known, it is impossible to calculate the percentage of persons attacked of the number who drank of the infected milk. If the infection of the milk by Fred J—— occurred July 1st, as appears from the servant seen by Dr. Miller July 2d, and who was attacked in Philadelphia July 17th, the period of incubation in the last case, which occurred on July 30th, would be long (twenty-nine days) if this were the only infection; but it is possible that he carried the germs to the milk at a later date also, and maybe more than once; for the period between the cessation of his milking and the appearance of the last case was just nineteen days. It is of curious interest that three of the victims disliked milk as a drink. One of them only took the milk with hominy at breakfast; another with berries at supper; and another, a cook, tasted the milk for the family when it was received in the morning.

Under date of September 12th, Mr. McGuire wrote that the "milk samples taken were found to be free from disease germs," and enclosed a copy of the report of the analysis of the waters made by Mr. Shippen Wallace, of Philadelphia, dated August 16th, from which I quote: "They all show the presence of nitrites, the amount of chlorine exceeds 3 parts per 100,000 in all, and the ammonia figures are beyond the limit." "In my opinion they are all unfit for potable use." "The water should not be used in connection with milk, unless thoroughly boiled before using to cleanse the cans." As far as could be learned, there was not one case of illness in the families drinking these waters.

SARCOMA OF ABDOMINAL CAVITY CURED BY TOXINS OF ERYSIPELAS.

By HERMAN MYNTER, M.D.,

PROFESSOR OF SURGERY TO THE NIAGARA UNIVERSITY, BUFFALO, N.Y.

The following case is so remarkable in its result that it almost makes one doubt the correctness of the diagnosis, notwithstanding the microscopical examination.

I was called, on July 20, 1894, to see Cora P——, twelve years of age, living in the neighborhood of Buffalo. The object of my visit, as stated by the mother, was to decide, whether an operation would give her a chance of recovery, and whether she in that case could be moved to the Sisters' Hospital in Buffalo. I found the patient a well-developed girl, extremely pale, and so short of breath that she for several weeks had been unable to lie down in bed. The mother stated that she had been a strong and healthy child up to March, 1894, when she had a fall which produced marked swelling in the left inguinal region accompanied with pain and causing much distress. The swelling did not subside, but increased gradually, while at the same time her health gave way; she lost appetite and strength, and was at last forced to take to her bed. The abdomen continued to enlarge; she became feverish, with hectic flush on her cheeks, increasing dyspnœa supervened, œdema of the legs appeared, and her condition became pitiable. Four weeks previously to my visits another Buffalo physician was called in consultation. He found the abdomen enormously distended, diagnosed ascites, but on puncturing the abdomen he got a dry tap. After the puncture the swelling increased more rapidly, and with it the dyspnœa, so that the child could not lie down. Urine passed involuntarily, temperature at visit 102° F.; pulse, 130, small and weak. On examination the lungs and heart were found normal, the dyspnœa evidently being the result of the enormously distended abdomen. The abdomen was evenly rounded and distended, with dull percussion in lower parts. An indistinct fluctuation was felt by tapping over the whole abdomen. The whole lower part offered more resistance, and an indistinct mass could be felt in both inguinal regions, and in front extending upward almost to a level with the umbilicus. On account of the fever, the rapid increase of size, with indistinct fluctuation and increasing marasmus, I thought it possible that we here might have a suppurating dermoid cyst, although the case had many characteristics of malignancy, and as a fatal issue seemed imminent I advised her removal in the ambulance to the hospital for the purpose of making an explorative laparotomy in order to clear up the diagnosis, and, if possible, save her life. Examination per rectum and vagina could not be made in her position.

July 22d.—Under chloroform narcosis explorative laparotomy was performed, a large number of well-known physicians and surgeons being present. Free in the abdominal cavity was found about two quarts of a thick, odorless, chocolate-colored fluid, and there was also an inoperable growth involving both the parietal peritoneum, the mesentery, pelvic organs, and cæcum. It was loosened partly from the right inguinal region, and a piece as large as a fist removed; but the bleeding was so terrific and the patient's condition so unfavorable that further attempts were out of the question. The abdomen was therefore hurriedly irrigated with sterilized water, the bleeding checked by tamponade with many yards of iodoform gauze, the wound closed, and the pulseless and livid child hurriedly removed to the ward in a dying condition. By active stimulation she revived again; but the case was by all present considered necessarily fatal. The removed piece of tumor had a soft homogeneous appearance, looking very much like white brain tissue, and was microscopically considered sarcomatous.

During the next three days the patient improved somewhat, probably on account of the diminished dyspnœa from the relief of the tension.

July 26th.—The wound was dressed and the gauze tampon removed, which was followed by a profuse discharge of the same kind of fluid previously described. A large glass drainage-tube was thereafter inserted, through which several ounces of the same fluid were pumped out every few hours. The same day I procured a supply of filtered toxins of erysipelas from Dr. Roswell Park, and commenced to use it on the patient, injecting every day one grain in the upper end of the femur. It was impossible to inject it into the deep-seated tumor itself. During the next week a quite astonishing event occurred. While there still was a profuse discharge of the fluid mentioned, necessitating pumping out every two or three hours, there commenced to be discharged through the drainage-tube large masses of necrotic tissue of the size of good-sized oysters. It became necessary to remove the tube frequently in order to pick out these necrotic masses, which would completely fill up and choke the tube.

August 7th.—It is noted in the journal that about one ounce of fluid, which now has more the character of pus, is removed every three hours, and with it large masses of necrotic tissue. The patient is remarkably improved, the tumor appears to be receding, the appetite is good and the abdomen very much smaller.

August 13th.—Abdomen irrigated with peroxide of hydrogen daily, and a large quantity of degenerated tissue continues to come away. The patient is greatly improved, the tumor seems to be rapidly melting away. Her appetite is good; pulse and temperature normal. The toxins do not produce elevation of temperature.

August 23d.—The discharge is diminishing, and less amount of necrotic tissue discharged. There is still felt some swelling deep in the pelvis, particularly on the right side. Patient otherwise steadily improving.

September 11th.—Discharge has almost disappeared.

September 17th.—Patient discharged to her home in excellent condition. She is a picture of health, with red lips, fleshy, and healthy-looking. A small fistula yet present, leading to a cavity containing about one-half ounce, into which a rubber drainage-tube is still inserted. No swelling can be felt in the pelvis, but there is still some infiltration in the anterior abdominal wall around the drainage-tube. There is no discharge except a small quantity of pus, and the abdomen is reduced to its normal size.

October 4th.—Patient continues in excellent health, drainage-tube has been removed, and the fistula superficially granulating.

The piece of the tumor removed was unfortunately lost, but some of the large masses discharged were submitted to Dr. F. J. Thornberry, who gives the following report:

Macroscopically the specimens comprise principally irregular and quite firm pieces of tumor of varying size, some of which have shredded margins. Microscopically are seen masses of round and elongated cells, with, in places, accumulation of brownish pigment granules. The appearance of round cells may be due to transverse division of elongated cells. In portions of the growth no cellular elements are discernible, the specimen having a coarse fibrous appearance. Blood-vessels through the tumor are quite numerous. Necrotic changes have taken place in some parts. From the histological character of this growth I would consider it sarcomatous.

Ice Creams and Bacteria.—Dr. Klein has been examining bacteriologically the ice creams sold in the public streets, and the water used for washing the glasses in which they were served. In all, six samples were examined, and in each sample such an abundance of pathogenic and other germs were found, that it led Dr. Klein to assert that they were not inferior to ordinary sewage. Many of the forms identified bore striking resemblance to those diagnostic of typhoid—if, indeed, they were not identical. In view of these facts the importance of careful legislative control over food provision cannot be overestimated.

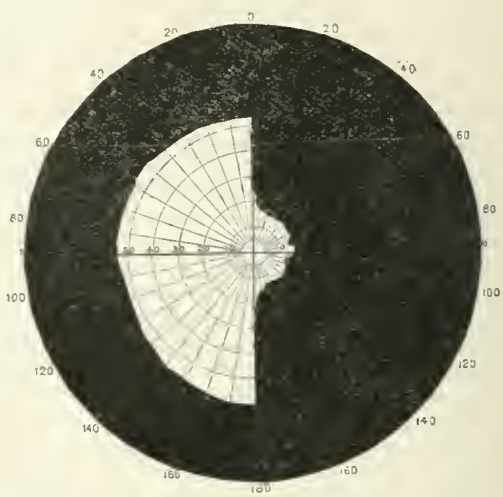
The Average Number of Medical Members of the Japanese House of Commons has hitherto, it appears, been three or four. At the last election, which took place on September 1st, only one (Dr. Wakizaka) was elected. Japanese doctors would seem to have even less taste for the political arena than their English brethren.

SYPHILOMA OF OPTIC CHIASM PRODUCING BILATERAL TEMPORAL HEMIANOPSIA.[1]

By CHAS. E. NAMMACK, M.D.,

ATTENDING PHYSICIAN OUT-PATIENT DEPARTMENT NEW YORK HOSPITAL.

William P——, thirty-four years of age, cloth examiner by occupation, applied February 20, 1894, for treatment on account of severe occipital headache, which had lasted twenty days with progressively increasing intensity. He also complained of fissures of the tongue, and gave the following interesting previous history. He had always been a moderate Saturday night drinker,



but seldom drank on business days. He had never had rheumatism. In October, 1889, he contracted a chancre, for which he consulted a physician, who recognized it as the initial lesion of syphilis, and at once instituted mercurial treatment. Six weeks later Mr. P—— was found unconscious in the bath-room, and remembers nothing of the events of the succeeding forty days, at the expiration of which time he found that he had paralysis of the right side. At the end of three months he was able to leave his bed. He then took from three to six one-quarter-grain pills of proto-iodide of mercury every day, until eleven hundred pills had been consumed. Iodide of potassium was next given him, in doses ranging from ten to twenty grains three times a day, until December, 1893, a period of four years from the time of his initial lesion. Treatment was then stopped. Four weeks later the headache, for which he came to the Hospital, developed.

Examination.—Fissures of the tongue have the characteristic appearances of late syphilis.[2] No apparent facial palsy. No tenderness to skull percussion. Pupils react normally to light and to accommodation. Sways slightly when standing with eyes closed. Staggers slightly to left in walking. Knee-jerks exaggerated. Ankle clonus present. Dynamometer records the same hand-grasp on the two sides. Patient states that he has had several narrow escapes from collision with vehicles approaching him from either side, and rough tests show the existence of bi-temporal hemianopsia. He is referred to Dr. Leroy Pope Walker for more accurate examination, and Dr. Walker reports that vision = $\frac{20}{20}$ in each eye. Color vision, normal. Fields of vision as shown in annexed perimeter charts.

The diagnosis is, therefore, gumma in the substance of the optic chiasm.[3] It is evident that the growth must be an infiltrating, rather than a compressing, neoplasm, in order to exactly split the middle fibres of the chiasm, and allow the morbid influence to remain limited to the central portion. The absence of paralysis of the adjacent motor nerves to the eyeball muscles

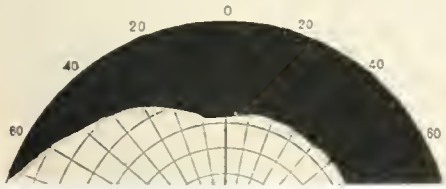
[1] Patient presented at meeting of New York Neurological Society, December 4, 1894.

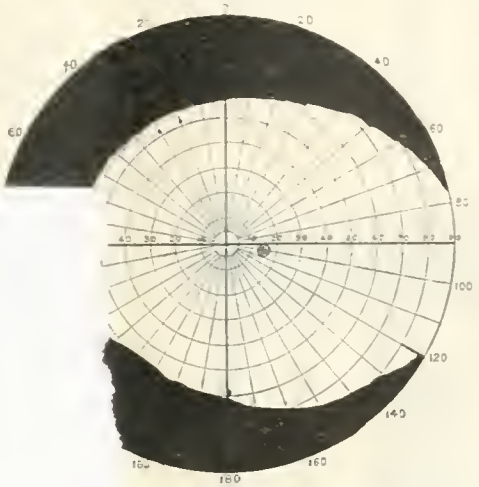
[2] Vide Fairlie Clarke, Diseases of Tongue, Figure 25.

[3] Vide Herter, Diagnosis of Diseases of Nervous System, p. 149.

would also indicate that the disease was within, rather than outside of, the chiasm.

The treatment ordered was inunctions of blue ointment, and iodide of potassium internally, the latter to be gradually increased in dosage until relief of symptoms or intolerance of drug had set in. He used two ounces of ointment at the beginning, and has used the iodide continuously since in doses of fifty drops of a saturated solution after each meal. The effect upon the symptoms was marked and rapid, except in the case of the tongue fissures, which showed their usual rebelliousness to local and general medication. Dr. Walker





greatest care, it is still impossible to do away entirely

[3] Professor Houston.

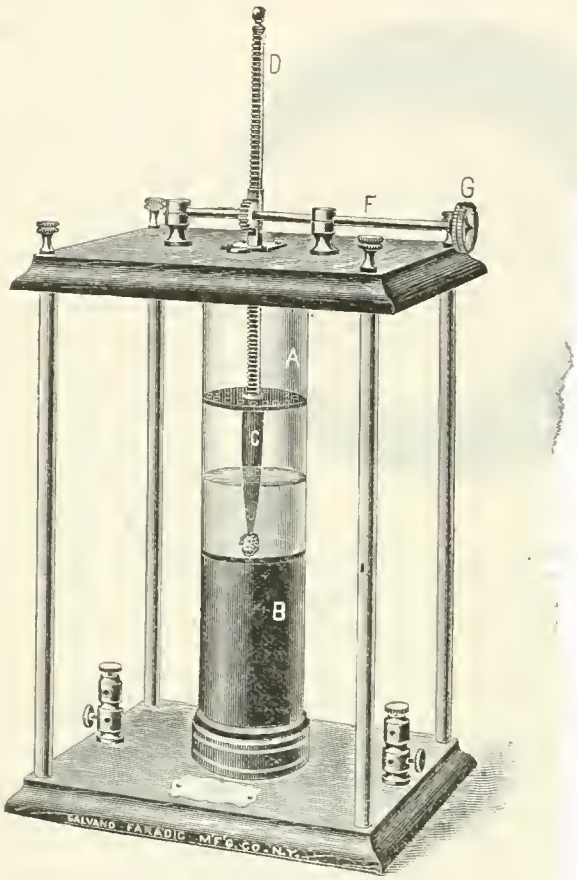
with sudden shocks and jars, which are painful to all in varying degrees, but especially to nervous, sensitive patients.

A certain amount of experimental work in conditions where a profound massage effect was desired, especially in pelvic conditions, convinced me that to obtain its full measure of usefulness, and thus to insure its highest therapeutic success, it was necessary to be able to regulate and control the volume or ampèrage of this current with the same nicety that is possible with the constant, induced, or sinusoidal current. Despite the difficulty encountered in securing this control of the static induced on account of its immense E. M. F., the writer undertook, in the early part of 1894, to make some experiments with various patterns of water rheostats, to see if by any possibility a regulator could be constructed on this principle, through which this current could be passed without the danger of spark leakage. The first experiments were made with the Bailey water rheostat, and I found that, so long as I kept my spark gap as short as the distance between the two milled screw heads, I could perfectly control it. The same thing was proven with other water rheostats, and the fact established that all that was necessary was to keep conducting material at the maximum sparking distance apart.

Finally, the instrument shown in the cut was constructed for me by the Galvano-Faradic Manufacturing Company of New York City. Enclosed in the glass tube *A* is a cup of pure carbon *B*. This cup is secured at the bottom and forms one of the terminals, the other terminal is a tapering carbon rod *C*, fastened to a metal rod *D*, and wrapped with a sponge at the apex *E*. On the top of the rheostat, connected with a coarse double-thread screw (a continuation of the metallic rod *D*), is a metal bar *F*, ending in a large milled screw-head *G*. By turning this screw head the carbon point is raised and lowered at will. The glass is filled with water until it touches the sponge on the end of the carbon rod. The rheostat is wired on the principle of a shunt circuit, and has double binding posts, one to receive the wires from the Leyden jars, the other for the conducting cords distributed to the patient. The rheostat may be connected directly with the machine in the room in which it is placed, or heavy well-insulated wires may be connected with the static induced binding posts, and carried through apertures in the wall to an appropriate place at a distance, keeping them at all times more than sparking distance apart. It may then be placed at a convenient point for daily use, by the right hand of one's operating-table, for instance, and connections made in that position with the wires from the machine. It is possible to use it with any size of the Leyden jars and a spark gap of from one to four or five inches. The latter, of course, is only desirable with the smallest jars, but with the longer spark gap the current loses the rapidity of its oscillations, but gains in E. M. F.

When the rheostat is permanently connected with the machine, as I have indicated, the first thing to do is to arrange the spark gap of the size desired and set the machine in motion, then connect the conducting cords from the rheostat to the electrodes through which the current is delivered to the patient. When all the connections are made for the administration of treat-

ment, the tapering carbon fastened to the metal rod is gradually raised by turning the screw until the current strength desired for the particular application is reached. This can be done to such an extent as to produce the most violent muscular contractions without the patient suffering from any pain, jars, or shocks. With appropriate connections every voluntary muscle of the body can be put into a state of activity, with the exception of a few muscles of the head and face, and the temperature raised from a fraction of a degree to two degrees. It accomplishes, in common with the usual administration by means of sparks, a most marked nutritional gain.



By its use all metabolic processes are encouraged. I vagino-abdominal applications, patients speak of th effect as much more pronounced than from either th induced or sinusoidal currents; an effect which the characterize as a feeling of lightness and buoyancy i the pelvis, with an ability to walk with greater ease. I is not well borne in subacute inflammatory condition of the pelvic organs. Patients with such trouble ar prone to have recurrence of pain and soreness, sav with the mildest applications.

The current best adapted to the treatment of pelvi conditions, where relief from pain is desired as well a. relief from congestion, is obtained by using the large or medium jars, standardizing the frequency by a ver small spark gap, say from one-eighth to one-half of a inch, and gradually turning on the whole available cu rent strength by adjusting the controller. Where pro found massage effect is desired, as in prolapsus uteri o relaxed vaginal walls, a longer spark of greater E. M F., but with less rapid oscillations, is of greater value and for such uses no other current can take its place By means of this instrument, when once the spark ga is arranged, the machine in motion, and the patient i circuit, the operator is able to make any application general, intra-uterine, intra-vaginal, intra-nasal, to the eye or the ear, and so perfectly regulate the current as to make the treatment absolutely painless.

As a result of the physical peculiarities of the static induced, it is impossible to place a resistance in the circuit without damping the oscillations. This damping-out effect I can readily appreciate both by ear and touch, but as I am in the habit of increasing the number of revolutions of my machine under these circumstances, I am able to compensate for any such loss and maintain sufficiently rapid oscillations to secure the same clinical effect as when there is no rheostat in circuit.

The form of the rheostat is not a new one, but an adaptation from a constant current controller already on the market. The features of originality to which the writer lays claim are the conception of the idea of regulating the current strength of the static induced without varying (in any practical degree) the frequency of the oscillations and the peculiar form of rheostat by which that idea is reduced to practice. This rheostat was shown at the New York Electro-Therapeutic Society last April, and at the American Electro-Therapeutic Association at the annual meeting in September.

68 Madison Avenue, December 15, 1894.

The Pasteur Institute has now a stud of one hundred and fifty horses all undergoing treatment for the preparation of the diphtheria antitoxin.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, February 9, 1895.

A NEW TREATMENT FOR CHRONIC JOINT AFFECTIONS.

A SOMEWHAT novel method of treating chronic rheumatic and gouty affections has been tried at St. Bartholomew's Hospital, and at the Northwest Hospital, in London. As described by Mr. Alfred Willett, the Tallerman-Sheffield local dry hot-air bath is an invention by which dry air at temperatures from 250° to 300° F. is applied to a portion of the body, such as hand or foot, knee or elbow, an arm or leg. The bath itself consists of a copper cylinder, varying in size and shape according to the part to be enclosed. At one end the limb enters, surrounded by rubber sheeting, and the other is closed by a movable cap working on a pivot, by the use of which, and outlets at the top and bottom of the cylinder, it is found possible to keep the air in the chamber practically dry throughout the operation, notwithstanding the moisture thrown off by the limb enclosed, and instant relief can be afforded the patient if the temperature causes any discomfort. The cylinder is heated by gas burners placed underneath. Precautions are taken to prevent the skin from coming into contact with the heated metal. Mr. Willett's conclusions are decidedly in favor of the treatment in certain cases, and his results may be summarized as follows: The first effect of the heat is to induce a copious diaphoresis; and the circulation of the blood in the part is enormously increased, as is well shown by the bright redness of the limb when removed from the bath. The anodyne effect is often remarkable: pain is generally not only relieved but entirely removed, so that the patient expresses the great relief he feels and moves the limb with much greater freedom and with much less pain. The cases that appear most likely to be relieved by the treatment are sprains, stiff joints (where there are no very strong adhesions), flatfoot, gonorrhœal rheumatism, acute and chronic gout, chronic ulcers, and rheumatism. It deserves also to be employed for its anodyne effect, after forcibly breaking down under an anæsthetic adhesions which have formed in or around a joint; if the limb be placed in the cylinder the pain, which is generally severe, is greatly lessened and the secondary stiffness is much diminished. Mr. Willett was of opinion that but little assistance would be afforded by this bath in overcoming firm, fibrous, articular adhesions. Sooner or later the adhesions will have to be forcibly broken down under an anæsthetic.

The treatment was applied at the Northwest London Hospital, by Mr. Mayo Collier, upon eight cases. The patients suffered from sprains, rheumatoid arthritis, gout, chronic leg ulcer, and tuberculous knee-joint. Improvement was reported in all cases, and in some it was quite striking.

THE VALUE OF PHYSICIANS ON HEALTH BOARDS.

FOR some weeks, says *The American Lancet*, the matter of a new law reconstructing the Detroit Board of Health has been under consideration. The physicians have uniformly held that the majority of the Board should be medical men. Many laymen, including the lay press, insist that there should either be no medical men or only a minority upon the Board.

Voicing the sentiments of the laity, the Detroit *Tribune* says: "The members of the Board of Health need primarily to know what the people expect of their department. Their necessary additional equipment is the force and zeal to exact from the department the service the people want. Medical knowledge or medical skill has no part in the work of the Board of Health. While a doctor might not find his technical acquirements a detriment in performing the duties properly devolving upon the Board, as has been rather unkindly suggested, it is certain that he would find them of no use whatever. The qualifications of a member of any commission are entirely apart from professional attainments."

Naturally, any medical journal which attempts to argue against this view will be accused of partiality. Yet we cannot understand how sensible people can accept the logic of the *Tribune's* argument. The primary need, it says, of members of a health board is "to know what the people expect of it!" We should say that the primary needs were a knowledge of how to prevent disease, and how to teach the people to live healthfully. This involves expert and technical acquaintance with the natural history of disease, organizing power, and executive skill. A health board without experienced medical men upon it would be an absurdity. The best suggestions for preventing disease and the best sanitary organizations have come from medical men. A law such as we have in New York, making it impossible for a medical man to hold the office of President of the Board of Health, is a strange anomaly, and has been a continued affront and source of irritation to the profession of this State. It is not that a good man could not be obtained as simply an executive of the board, but that a medical man should be specially prohibited from holding such an office, whether qualified or not, merely, it would appear, because he might, under all other circumstances, be justly entitled to an exclusive right in that direction. The distinction is quite invidious from every other point of view than the purely political one.

Dr. Zacharin, one of the medical men in attendance on the late Czar of Russia, is reported to be worth 7,000,000 roubles, which he has made in the practice of his profession

WOMEN BACTERIOLOGISTS.

The public seems very much surprised and interested by the fact that a woman physician has been appointed among the bacteriologists of the City Health Board. Bacteriology, however, is not a very mysterious or difficult science, and there is no reason why any well-educated physician, male or female, who pays attention to this specialty, should not succeed in it. Bacteriological and microscopical work require a certain orderliness of habit and nicety of touch, faculties which it is to be supposed women pre-eminently possess. Women, however, have never pursued these branches of study very eagerly, and we do not recall any great contribution either to pathology or bacteriology that they have made. Perhaps this is because poverty has always been the handmaid of pathology, and has been about the only maid the pathologist could afford to have.

Dr. Anna Williams, untrammelled by any of the usual drawbacks of fame or fortune, has now an opportunity to distinguish herself in this new line of work. Her qualifications are of a high order, and she will doubtless vindicate the principle upon which her appointment is based.

STAMP-COLLECTING AS A CHARITABLE MEASURE.

It is a pleasure to learn that Miss Mollie Gunderson, of North Dakota, has succeeded in collecting two million stamps, and has left for Chicago to have a pair of artificial legs fitted to her.

But, incidentally to the success of Miss Mollie, there has developed a mania for stamp-collecting as an eleemosynary measure which threatens to become an intolerable nuisance. We learn, for example, that some time ago a lady thought to amuse and help her invalid sister by starting a stamp-collecting movement. She, therefore, invented a story to the effect that her sister was suffering from a chronic disorder which was curable by surgical operation, and that this operation would be undertaken by a certain hospital if the invalid could collect a million of stamps. So she organized a "chain of three."

The story passed from town to town and State to State. The stamps began to come in at first by hundreds, then by thousands. A million were obtained, then another and another, until now the patient has over eight million of stamps, and they still come in daily by the thousands. It is the old story of the salt-mill which ground and ground till the house was full, and the yard, and the barn, and the fields, and finally the ocean itself. The Kansas lady is obliged to resort to bonfires for protection.

We deprecate the further use of stamp-collecting as a charitable measure.

Organization of the Hospital Staff Association of Western Pennsylvania.—An organization of the staffs of the public hospitals of Pittsburg and neighboring towns into one association, has recently been consummated. The officers of the Association are : *President*, M. O. Jones, M.D. ; *First Vice-President*, J. H. McClelland, M.D. ; *Second Vice-President*, W. S. Huselton, M.D.; *Secretary*, C. C. Hersman, M.D.; *Treasurer*, I. J. Moyer, M.D.

INSTRUCTION IN HYGIENE AT WEST POINT.

The annual report of the Board of Visitors to the United States Military Academy for the year 1894, contains a suggestion from the Committee on Hygiene and Athletics which we hope to see acted upon. The committee, whose chairman was Dr. W. M. Keen, learned upon inquiry that the instruction in military hygiene and first aid to the injured which the cadets received, was of the most meagre and fragmentary nature—far inferior, indeed, to that imparted to private soldiers by the medical officers of the different posts. The entire instruction during the past year consisted in six advance and five review recitations in physiology and hygiene, certain incidental allusions to the principles of ventilation, heating, choice of sites for camps, etc., by the professors of chemistry and engineering, and one lecture on first aid by one of the medical officers. One need not be a medical man to see that no practically useful knowledge of sanitary subjects can be acquired from such haphazard teaching as that. As well might one learn anatomy from the pictorial advertisements of lung balsams and liver regenerators in the daily papers. It is true that some instruction in sanitation is given to the young lieutenants at certain posts after graduation, but not at all posts ; no complete course, however, is given at any such post of instruction, nor are all the graduates sent to these post-graduate schools. The Military Academy is the place where such instruction should be given, for here only can it be uniform and systematic.

In this matter of instruction in hygiene and sanitation West Point may well take a lesson from Annapolis. At the Naval Academy there is a regular course of physiology and hygiene conducted by one of the medical officers of the Navy. The course begins with several lectures on biology, and is followed by instruction in anatomy and physiology. After the cadets are sufficiently grounded in these subjects, they attend lectures on general and naval hygiene, and the course terminates with practical instruction in first aid to the injured. In all, about thirty lectures are given during the year, and the attention of the cadet is assured by means of monthly written examinations on the subjects treated of in the lectures.

The importance to the future naval or military officer of at least an elementary knowledge of these subjects is self-evident, and it seems strange, in this age of sanitary advance, that they should be neglected—and almost incredible that there should be any opposition to the establishment of some such course at West Point, after the defect has been brought to the notice of the authorities. Yet, that there is opposition is evident from a letter of the Superintendent of the Academy incorporated in the report. The reasons for his opposition are not stated in the letter, so we can only surmise what they are. To judge from the recommendation of the committee, however, the main objection would seem to be that no time can be found for sanitary studies without curtailing the instruction given in other departments. A number of hours are devoted to the study of mineralogy, geology, and French, and surely some of the time given to these branches might profitably

be spared for instruction in the art of preserving health.

This is the view taken by the committee, and we do not see how any reasonable man, however conservative he may be, can take objection to their modest recommendations. The committee recommended that a chair of anatomy, physiology, hygiene, and first aid to the injured, be established at West Point, that it be filled by the senior surgeon, and that the course should cover at least thirty lessons and demonstrations. To gain the necessary time for this course, the committee further recommended that the eleven recitations on hygiene now held by the professor of chemistry, be given to the proposed chair, and that the remaining hours be taken from the courses on mineralogy and geology. The study of these two subjects, while doubtless very desirable in a general way, is of far less importance to a future leader of large bodies of men than that of sanitary science. It is true that the matter of hygiene is more especially the province of the surgeon of a post. But some small posts have no medical officer, and in any case the army surgeon is a subordinate who can work for the greatest good of the men whose health is entrusted to his keeping only when his hands are intelligently upheld by his commanding officer.

FIRE IN A HOSPITAL.

A FIRE occurred in the Deaconess's Hospital at Cleveland, O., on February 1st, and almost destroyed it. Three patients and one nurse lost their lives. The accounts say that the nurses got out safely, almost at the start, with the exception of Minnie Baumer. When her sister-nurses called to her that the building was on fire she cried, "No, I will not leave my patient—I will die first." She was nursing Krause, who was also burned to death. She sat by the side of the sick man until death came to both of them. The act was a brave and heroic one, and it might well inspire the orator to eloquence and the poet to verse. But was it necessary? Should the nurse feel that she had no right to her life because her patient had no chance for his? Most people would say no, and yet it is such acts as these that stir enthusiasm and renew faith in the nobility of human nature.

News of the Week.

Antiseptic Treatment of Diphtheria.—Dr. C. J. Proten writes: "In the recent issue of the MEDICAL RECORD (page 119), are recorded some remarks which I indulged in, at a discussion of a paper read by Dr. Amende on 'A Treatment of Diphtheria upon Antiseptic Principles.' Among other remarks you quote me as saying, 'that the application could not reach the nose nor the larynx and was *less* harmful than irrigation of the nose.' What I did say was as follows: 'that the applications, as practised by the author, could not properly disinfect the pharyngeal cavity. Besides, no allowance was made for disinfection of the nose and naso-pharynx, when this locality was affected. That such applications were conducive and favored an extension of the disease owing to the infliction of traumatism, which necessarily follows, and were far *more* harmful than irrigation of the nasal passages.' I am simply misquoted in saying less harmful than more harmful, which gives the statement a different color. A statement of this sort would and should be subject to just criticism, if it were to go unchallenged. The author of the paper read, recommended an ordinary small size camel's-hair pencil, as usually used for painting iodine to the surface of the body."

The Society for the Relief of Widows and Orphans of Medical Men of New Jersey.—This society was incorporated in 1882, and has continued to grow both in influence and membership. Since its organization 241 physicians of the State have become members; of which number 22 have died, 28 been dropped for various reasons, leaving at the present time 191 active members. The permanent fund amounts to $1,338.42, and it is intended eventually to allow small annuities to widows and minor children in cases of need. The amount already paid to the families of deceased members amounts to $2,478.00. The total cost of running the society during the past year was $19.67.

The Late Dr. Loomis.—At a meeting of the Faculty of the Medical Department of the University of the City of New York, held January 25, 1895, the following preamble and resolutions were adopted:

Whereas, In the wisdom of Almighty God it has been decreed to remove from among us our esteemed and honored associate, Dr. Alfred L. Loomis, who has been for thirty-three years identified with the progress and development of the Medical Department of the University of the City of New York, and to whose untiring energy and zeal that institution largely owes its present high position, we, the members of its Faculty hereby

Resolved, That in the death of Dr. Loomis we have met with an irreparable loss, in one whom we have ever valued as a friend, respected for his judgment and wise counsel, and admired for his strength and firmness of character, for his professional skill, his scientific learning, and his literary attainments.

That while overcome with a sense of personal bereavement, we are not unmindful that the medical profession throughout the country has lost its foremost leader, and the public a distinguished citizen. And be it further

Resolved, That this resolution be spread upon the minutes of this meeting, and that a copy be suitably engrossed and sent to the family of Dr. Loomis in token of our profound sympathy and sorrow.

Sibley Memorial Hospital, at Washington, D. C., corner of North Capitol and Pierce Streets, was formally opened for patients on February 1st.

Iowa State Medical Society.—The forty-fourth annual meeting of the Iowa State Medical Society will be held April 17th, 18th, and 19th, in Creston, Ia. The following are the chairmen of the different sections for the next meeting of the State Society: Medicine, F. M. Hiatt, Red Oak; Surgery, J. M. Emmert, Atlantic; Obstetrics and Gynecology, H. L. Getz, Marshalltown; Ophthalmology and Otology, H. B. Young, Burlington; Materia Medica, J. R. Guthrie, Dubuque; State

Medicine and Hygiene, J. S. Braunsworth, Muscatine: Mental and Nervous System, F. S. Thomas, Council Bluffs.

The New Medical Bill for the District of Columbia.—The Commissioners gave a hearing on the 11th ult. to a number of medical men representing the Medical Society of the District and the Homœopathic Society, on the various bills now pending before Congress to regulate the practice of medicine.

Free Medical Education in Denver.—It is certainly very unfortunate, and surely very much to be regretted, not only in the interest of the medical colleges, but in that of the medical profession as well, that there should be a medical college in Denver granting free tuition to all students residing in the State of Colorado, and practically to all students from without the State. This condition of affairs necessarily lowers and belittles the standard and standing of our medical colleges, inasmuch as the other schools, in order to compete with the free institution, must of necessity cut fees.—*Denver Medical News.*

Harvard Medical Society of New York City.—At the annual meeting of the Harvard Medical Society, held January 26th, at Harvard House, the following officers were elected for 1895: *President*, Dillon Brown, M.D.; *Vice-President*, Charles L. Gibson, M.D.; *Secretary*, Theodore Dunham, M.D.: *Treasurer*, George E. Brewer, M.D.

Arrested for not Reporting Cases of Small-pox.—A physician of this city, whose name we do not find in the County Society's Directory, has been arrested for failing to report several cases of small-pox. The act is a misdemeanor.

A Decrease in the Mortality of Diphtheria and Croup Cases.—Since the introduction of the use of antitoxin in diphtheria and croup cases, a marked decrease in the mortality of children suffering from the two diseases has been noticed by the Board of Health. From December 15, 1894, to January 12, 1895, the total number of cases reported was 933, with the number of deaths as 273, or twenty-nine per cent. From January 12th to January 26th, 640 cases were reported, of which 119 proved fatal. The death-rate, however, was reduced to twenty-one per cent.

The Guinea-pig Supply.—For the manufacture of antitoxin guinea-pigs are needed. Fanciers, who dealt in pigs, have supplied the market, but the supply is not equal to the demand. Fame and fortune, the health authorities say, await the boy who will raise guinea-pigs for use in the laboratory. Seventy-five cents is paid for a healthy pig two months old. A pair for breeding purposes cost $1.50. The female litters four times a year, with four in a litter, but one of the number dies shortly after birth. It is almost impossible to get a guinea-pig for use in the laboratory at present. In a few months, however, the market will be overstocked, and we advise the small boy to proceed with caution.

The Animal Extracts.—Drs. T. G. Shoemaker and H. C. Wood report, in the *University Medical Magazine*, a case of Addison's disease greatly relieved by injections of an extract of the supra-renal capsules, and a case of Graves's disease nearly cured under the use of extract of the spleen.

Death of Dr. George W. Topping.—Dr. Topping, a former president of the Michigan State Medical Society, and a well-known figure at all medical gatherings in the State, died suddenly at his home in De Witt, Mich., January 14th. Few men stood higher in the profession or were more generally loved and respected.

The Death of Dr. B. W. Palmer, of Detroit, Mich., took place at Nyack, N. Y., January 4th. Dr. Palmer was a well-known practitioner and writer, and was for several years editor of *The Medical Age.*

Dr. M. C. Rowland, of Geneseo, N. Y., died on January 15, 1895, aged sixty-seven.

Dr. Joseph H. Dunnigan, of Buffalo, died of diphtheria, contracted while attending a patient, on January 4, 1895. He was born at Greenwood, N. Y., in 1864. Dr. Dunnigan was treated with antitoxin, but without success.

Dr. David W. Miner, of Ware, Mass., died on January 2d, aged seventy-four.

Dr. Lyman J. Barrows, of Janesville, Wis., died on January 15th, aged sixty-nine. He was born in Otsego, N. Y., and was a graduate of Williams College and Buffalo Medical College.

Dr. J. M. Eaton Dead.—Dr. John M. Eaton, an eminent surgeon and specialist, died in Denver, January 12th, of congestion of the brain and peritonitis. Dr. Eaton was once coroner of San Francisco.

That Day is Lost when St. Louis does not organize a new medical school. The latest is known as the "Practitioners' School of St. Louis."

The Charter of the New York Hospital.—This ancient document, granted in 1771 by George III. of England, has been in great danger of irretrievable ruin, but fortunately it has now been restored and so cared for as practically to insure its perpetual preservation. It has been carefully repaired by an expert and now hangs in the hospital library.

It is Proposed to Erect a Statue to the late Professor von Helmholtz. *Nature* states that the German Emperor has offered to head a subscription list for that purpose with a donation of 10,000 marks ($2,500).

Castration for Hypertrophy of the Prostate.—It is curious how long it takes to make the operation of castration popular even among persons above fifty-five. The operation of castration for hypertrophied prostate was first devised by Dr. White, of Philadelphia, in 1893, but as yet only thirteen operations are reported, despite the good results so far almost uniformly obtained. Ovariotomy will, we are sure, always be more popular.

The Production of Antitoxin for Boston.—Five horses were inoculated with diphtheria toxin at Gallop's Island on January 25th, as a first step toward the production of antitoxin by the Boston Board of Health.

The Next International Congress is to be held in Moscow in 1896; the President will be Dr. J. Th. Klein, Dean of the Faculty of Medicine. The Local Committee on Organization has chosen as its President, Count P. A. Kapnist.

Reviews and Notices.

Obstetric Surgery. By Egbert H. Grandin, M.D., Obstetric Surgeon to the New York Maternity Hospital; Gynecologist to the French Hospital, etc.; and George W. Jarman, M.D., Obstetric Surgeon to the New York Maternity Hospital; Gynecologist to the Cancer Hospital, etc. With eighty-five illustrations in the text and fifteen photographic plates. Pp. viii.–207. Philadelphia: The F. A. Davis Co., Publishers. London: F. J. Rebman. 1894.

"The key-note of this volume is election in obstetric surgery." This is the opening sentence of the preface, which will at once arrest the attention of those teachers of obstetrics who believe that the time has come when midwifery should be regarded as an exact science rather than a collection of aphorisms. After a careful perusal of the book we have no hesitation in affirming that the author's plan is clearly and consistently developed throughout. It is thoroughly practical, and reflects the experience of the bedside rather than the work of the library. With all due respect to our elders in the profession, too much responsibility has been thrown upon "Nature" in the management of labor-cases. Nature is a tricky jade. We are beginning to learn that it is often wiser to forestall her treachery than to allow her full liberty. How many mothers and children have been sacrificed by a reliance upon natural forces, which never have, and never can, effect delivery under the unrecognized abnormal conditions present!

It is with such cases in mind that we hail with pleasure the advent of the terse, forcible lessons in elective obstetrics as are contained in this work. As space forbids us to review it at length, we can only call attention briefly to its salient points of excellence.

The introduction on asepsis and antisepsis, and the initial chapters on pelvimetry and the induction of premature labor, are especially commendable. Chapters III. and IV., on forceps and version, contain just those practical points for which the physician looks in vain in the text-books. Symphyseotomy, Cæsarean section, and embryotomy, are fully discussed in separate chapters.

A chapter on the surgery of the puerperium is a new departure in an obstetric work, and a most praiseworthy one, since the subject is treated from the standpoint of the gynecologist, as well as of the obstetrician. We have always held that the careless repair of lesions of the soft parts after labor is responsible for a considerable proportion of female ills. The concluding chapter on ectopic gestation is a very fair presentation of this important subject.

The illustrations are numerous, clear, and helpful, the authors' style unusually lucid and forcible. That their views are thoroughly safe and modern, goes without saying. We predict a wide popularity and general approval of their work.

Essentials of Diseases of the Skin, including the Syphilodermata, Arranged in the Form of Questions and Answers, Prepared Especially for the Students of Medicine. By Henry W. Stelwagon, M.D., Ph.D., Clinical Professor of Dermatology in the Jefferson Medical College; Physician to the Department for Skin Diseases, Howard Hospital; Dermatologist to the Philadelphia Hospital; Physician to the Service for Skin Diseases, Northern Dispensary, etc. Third Edition, revised and enlarged, with seventy-one letter-press cuts and fifteen half-tone illustrations. Philadelphia: W. B. Saunders. 1894.

This is another of the handy question compends introduced by this publishing house. The first edition came out in 1890, and was so well received that the author has been encouraged to improve upon his original work wherever necessary, and to add a number of illustrations which do much to increase the attractiveness of the book. It is essentially for students, and the arrangement by questions and answers makes it a sort of home quiz.

State Board of Health of Massachusetts. Twenty-fifth Annual Report. Boston: Wright & Potts. 1894.

An unusually large volume of over six hundred pages, mainly devoted to reports upon water-supply, sewerage, and kindred subjects. Twenty-seven pages of index make reference to the various subjects a matter of ease.

A Compend of the Practice of Medicine. By Daniel E. Hughes, M.D., Chief Resident Physician of the Philadelphia Hospital; Physician in Chief to the Insane Department of the Philadelphia Hospital; Late Demonstrator of Clinical Medicine in the Jefferson Medical College; Fellow of the College of Physicians of Philadelphia, etc. Fifth Physicians's Edition. Thoroughly revised and enlarged, including a very complete section on Skin Diseases, and a new section on Mental Diseases, Philadelphia: P. Blakiston, Son & Co. 1895.

A handy, neatly printed volume, with text in fluent, easy style. The author shows considerable familiarity with mental diseases, and the short chapters illustrating the various forms of insanity are attractively written. When we turn to the part which is said to be "a very complete section on Skin Diseases," we feel that the "very" must be pronounced without accent.

In a casual search we fail to find mention of alopecia, pityriasis rosea, or rubra pilaris, dermatitis herpetiformis, eczema seborrhoicum, molluscum contagiosum, and many others.

It is well to add a chapter on the Skin Affections, but it is scarcely fair to tell the reader it is "very complete," unless at the same time you tell him what intonation to give the "very."

Report of the Ninth Annual Meeting of the Association of Executive Health Officers of Ontario, Held at Chatham, Ontario, August 14 and 15, 1894.

The usual questions relating to health are reported upon and discussed.

Transactions of the American Otological Society. Twenty-seventh Annual Meeting, Arlington House, Washington, D. C. Vol. VI. Part I. 1894.

Contains the papers read at the last meeting and the discussion upon them.

Fifth Annual Report of the State Board of Health of Florida, Jacksonville, March 31, 1894.

Contains 56 pages of Health Officer Porter's Report and 56 pages of Appendix.

Transactions of the Medical Society of the State of Pennsylvania at its forty-fourth annual session. Philadelphia, 1894.

Four Hundred and Forty-two pages, including index, neatly bound, giving a number of excellent papers.

Defective Speech and Deafness. By Lillie Eginton Warren. Pp. 116. New York: Edgar S. Werner, 1895.

Miss Warren's little book, indeed, fills a long-felt want. In her long experience as a teacher of aurally defective persons in this city, she has had a wide range of experience and, therefore, speaks from practical knowledge

of the subject. She has found that there are many deaf children in the schools who are not conscious of the fact; and for that matter the teachers themselves often are not informed upon the subject, but treat such pupils as dull and inattentive, with sad results. In fact nothing can be more discouraging to a child than struggling to get an education when the teacher pays no attention to its deafness; does not address it in a tone of voice to be heard, and, perhaps, seats it at too great a distance. This, however, is an abuse but little greater than the practice of some public schools for the deaf, where children with considerable hearing left are taught, and exhibited, along with totally deaf pupils as examples of deaf-mute teaching.

Miss Warren includes in her manual the training of stammerers as well as that of deaf-mutes and dull pupils, so-called. Sign and finger spelling receive attention, as well as teaching the dumb to speak.

The hard of hearing adult will be glad to learn that a chapter is given to explain how they may enjoy conversation. There are chapters also on stuttering, lisping, and careless speech in general. Naturally, cleft palate and other defects of the speech organ are considered from the teacher's point of view.

The whole subject of deaf-mute pedagogics is clearly considered in the light of modern science and experience.

A Text-Book of Pathology; Systematic and Practical. By D. J. Hamilton, M.B., F.R.C.S.E., F.R.S.E.; Professor of Pathology, University of Aberdeen. Copiously Illustrated. Vol. II., Parts I. and II. New York and London: Macmillan & Co. 1894.

Those who have had the first volume of this important work on Pathology must have eagerly awaited these two parts to complete the set, but there will be a compensating gratification when they find with what conscientious care the arduous labor necessary for its completion has been accomplished.

Almost all of the drawings (and they are very numerous) have been executed by the author himself. This in itself is a work of no small magnitude, and if we stop to consider the vast amount of laboratory work which made the drawings possible, the surprise is rather that there was not more delay.

The diseases of the special tissues and organs is here completed, and a chapter is added on malformations, and another on diseases of the fœtal membranes and placenta. Then follow "Diseases caused by Vegetable and Animal Parasites," "Animal Heat and Fever," "Systematic Bacteriology," etc.

A good feature is the reference to the source from which each statement of importance has been taken. The key to the number of references in the text includes 665 titles of publications. The whole number of pages is 1139. The press-work is well executed.

The Pocket Anatomist, Founded upon "Gray." By C. Henri Leonard, A.M., M.D.; Professor of the Medical and Surgical Diseases of Women and Clinical Gynecology, Detroit College of Medicine; Gynecological Surgeon to the Michigan College Hospital; Member of the American Medical Association, etc. One hundred and ninety-three Illustrations. Eighteenth Revised Edition, containing Dissection Hints and Visceral Anatomy. Detroit: The Illustrated Medical Journal Co.

The paper is so thin in this edition that the print, and especially the illustrations, show through in such a way as to endanger a student's eyesight.

Roux's Method.—The Republic of Uruguay has commissioned Drs. J. Rodriguez and Turenne to study M. Roux's method at the Pasteur Institute in furtherance of his work, and its example has been followed by Versailles.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Eighty-ninth Annual Meeting, held at Albany, February 5, 6, and 7, 1895.

George Henry Fox, M.D., President, in the Chair.

First Day, Tuesday, February 5th.

President's Inaugural Address.—Dr. Fox, in his inaugural address, stated there had been no special change in the medical affairs of the State during the year. In medical education an important advance had been made by one of our colleges in extending the course to four years. It did not follow, however, that all the other colleges ought to do the same. There was no unanimity of opinion in regard to what should be the length of the course, nor as to the methods of teaching and requirements for graduation, further than that there should be a solid foundation in each case.

Another great advance in medical instruction in the State, of recent years, had been instituted by the two post-graduate schools in New York City. The value of the work done by these institutions could not be over-estimated.

The President made two suggestions for the consideration of the Society, but did not recommend immediate action. The first related to the method of transacting routine business, which at present frequently consumed much valuable time of the Society. The method adopted by the Medical Society of the County of New York was suggested, of having routine business first considered by the *comitia minora*. A similar committee might be appointed by the Society, to consist of certain officers, reinforced by members from the different districts.

The second suggestion related to nominations for president. It was an honor to be president of this Society, but he thought those who had preceded him in the office were of his opinion, that the honor would be still greater if the selection were made by full vote. The method adopted by Yale, where the selection was made by the alumni, might be applied in a way to allow all the members of the Society to vote by mail.

Another suggestion was made which ought to be acted upon at once, namely, changing the date of meeting to a week earlier or a few weeks later, at a time when the hotels in Albany were less crowded.

He approved of the Secretary's suggestion, asking authority to turn the exchanges over to the State library. The death-roll during the year had been large. The death of Dr. Loomis, especially, was a great blow.

In arranging the scientific programme no attempt had been made to present a large number of papers, as it was desired rather to call out a full discussion.

Committees.—The following committees were then appointed: On Business, Drs. Phillips, Elsner, Pratt; on Credentials, Drs. Perry, Willard, Avery; to Recommend State Examiners, Drs. Flood, Slocum, Currier, Waldo, and Roe; on President's Inaugural, Drs. Suiter, Ward, Jacobi, Lewis, and Ely.

A Few Practical Points in the Diagnosis and Treatment of Pelvic Hæmatocele, with Report of a Case.—Dr. W. E. Colegrove named, among the causes of pelvic hæmatocele, rupture of vessels, sudden cessation of menses, ruptured extra-uterine pregnancy, rupture of aneurism, reflux of blood from uterus or tubes, or, in general, the hemorrhagic diathesis. The varieties were, extra-peritoneal and sub-peritoneal. The former was the more dangerous, but the latter was also to be regarded with suspicion.

The author's case occurred in an unmarried woman who felt pelvic pain and had some shock on alighting

from a carriage, and was pronounced by the physician who first saw her to have acute retroversion of the uterus. Dr. Colegrove saw the woman on the fourth day, found the cervix not in usual position of retroversion, and diagnosed pelvic subperitoneal hæmatocele. There was a hard round tumor posterior to the cervix, completely obstructing the bowel. Absence of fluctuation was to be accounted for by absorption of serum, leaving a hard clot. There was indication of commencing sepsis in rise of temperature to 103° F. He opened the tumor, cleaned out the clots, instituted drainage, and the patient recovered completely in ten days.

Dr. A. F. Currier fully approved of the treatment in this case, and especially of making incision per vaginam instead of supra-pubic. Usually, however, subperitoneal hæmatocele recovered under proper hygienic measures, without surgical interference.

The Use of Chlorine in the Treatment of Typhoid Fever.—Dr. R. W. Wilcox read the paper. It had been supposed that chlorine would cause irritation of the mucous membrane of the gastro-intestinal tract as it had of the respiratory tract on inhalation. Experience has shown, however, that it could be taken in quantity sufficient to be antiseptic and stimulant to certain organs without producing injurious effects. It penetrated all the tissues of the body, even to the brain, when taken internally. It quickened respiration, pulse, and excited the function of the organs of secretion, notably increasing the flow of saliva and bile. It corrected the fetor of certain products of fevers, and prevented absorption of infective materials from the intestinal tract. By its action upon the kidneys it caused more rapid elimination of toxins.

In typhoid fever the use of chlorine in moderate doses caused a fall of temperature, calmed nervous disturbance, helped digestion, cleaned the tongue, acted favorably on the ulcers, shortened the duration of the disease. The author had used it in four cases, aqua chlorinata of United States Pharmacopœia, one to four fluid drachms every two to four hours.

The Care of the Ears During the Course of the Exanthemata.—Dr. Wendell C. Phillips, in a paper on this subject, said the frequent dependence of ear trouble upon the exanthemata was shown by the statistics of the Royal Hospital for Sick Children, in Glasgow, Downie having analyzed 600 cases, 431 of which originated during measles, 63 during scarlet fever, and so on.

It was not the object of his short paper to give more than an outline of the treatment of the ears during the course of the exanthemata, especially measles and scarlet fever. Patients affected with these diseases exhibited a general inflammatory condition of the entire nasal and naso-pharyngeal mucosa, frequently extreme induration, both of which had a marked tendency to involve the Eustachian tubes. Enlarged tonsils and lymphoid tissue were apt to become much increased and further aggravate the symptoms. The secretions retained in the tympanum because of narrowing of the tube, caused pressure, pain, and the usual symptoms accompanying middle-ear inflammation. By way of prevention he recommended the following: Frequent thorough cleansing of the naso-pharynx; the child should frequently blow the nose. Dr. Phillips thought there was danger in Downie's suggestion to use the Politzer method, unless, indeed, inflammation already existed in the middle ear. Keep the tubes free from obstruction, if possible, from the first. This depended upon thorough cleansing of the naso-pharynx with a spray or douche of antiseptic solution, like Dobell's, boracic-acid solution, diluted listerine, or baptolene, alternating hourly with medicated oily sprays.

Where acute suppurative otitis had actually developed, the usual methods of treatment had to be resorted to.

Dr. J. E. H. Nichols would use a little cocaine to shrink the swollen nasal mucous membrane, thus aiding in clearing the nose, and also to allay any pain.

Tubular Cork Splints for Deformities of the Nasal Septum.—Dr. T. Passmore Berens, of New York, in a paper with this title, recommended cork as a material for nasal splints in preference to harder materials, and gauze or oakum, because of its elasticity, cleanliness, and adaptability to the required form. It was very convenient in emergency cases of injury to the nose.

Dry Treatment of Otitis Media Suppurativa.—Dr. J. E. H. Nichols read the paper. By dry treatment he did not mean cleansing the ear and blowing in boracic acid, a treatment which was attended by certain objections. The general line of management at the hospital consisted in cleansing the ear thoroughly, using peroxide of hydrogen, dry cotton, and wiping out of the ear subsequently, when moist, with cotton. This did away with heat and moisture, which was necessary to successful treatment of these cases. Liquid applications should be cleansing, antiseptic, and drying. Inflation should be used with discretion.

Care of the Nose and Throat During the Course of the Exanthemata.—Dr. C. C. Rice read this paper. The treatment recommended related to cleanliness, antisepsis, prevention of too rapid evaporation, lubrication, allaying of irritation, rendering of secretions alkaline. Seiler's solution as simple spray was recommended, to which might be added a little cocaine. Oily solutions were to be used as protective and lubricating. In their stead compound sterate of zinc powder was desirable in some cases. For warm steam he preferred the old croup-kettle principle. To solutions might be added either menthol, carbolic acid, thymol, eucalyptol, etc.

The Surgical Indications in Neuralgia.—Dr. J. G. Clark, of Olean, mentioned in this paper the several different operations done recently by various surgeons for the relief of trigeminal neuralgia, especially by excision of nerve after trephining of the temporal bone. In his own case, after excision of part of the nerve, he inserted the cautery into the proximal tract of the nerve. This man had had about all his teeth extracted, and had become addicted to opium. This was a common history in trigeminal neuralgia. Such faulty treatment, the author thought, must give way to surgical measures (excision of the nerve).

Dr. A. D. Bristow, of Brooklyn, had witnessed many operations for trigeminal neuralgia, and while relief was always obtained for a time, there was perhaps invariably recurrence. Some of the operations were not without danger, and he knew of three deaths. In Dr. Keen's case, referred to by the author, there had been much hemorrhage which was controlled by gauze tampon pushed in against the frontal lobes. No interference with brain function was noticed, except slight aphasia.

Extraordinary Intubation.—Dr. William Hailes, Jr., of Albany, reported two cases of intubation under this title. The first was a case of asphyxia in a child, two years of age, in which the following explanation was given: An embolus occurred after intubation, occluding the popliteal artery, which resulted in gangrene and necessitated amputation. It was believed there had been white thrombus in the heart, probably on the aortic valve, which caused both cardiac and respiratory difficulty, and a part had reached the popliteal artery.

The second case was one of typhoid fever in a man who, in the course of the disease, was taken with great difficulty of breathing. On attempting to do intubation the tube was arrested, and it proved to be due to cicatricial tissue, with destruction of the right arytenoid and right vocal cord. The diagnosis was confirmed subsequently by Dr. O'Dwyer and others. Asphyxia had been meanwhile relieved by tracheotomy.

Dr. Root, who had seen this patient, said perichon-

dritis was not rare, but it was rare for it to follow typhoid fever.

To Enforce a Law.—Dr. Lucian Howe, of Buffalo, offered the following resolution, which was adopted: That a committee of five be appointed whose duty it shall be to call attention to existing laws for the prevention of blindness from ophthalmia neonatorum, and to conduct the prosecution, or urge such, in cases of violation of the law.

In explanation, he said the present law was practically a dead letter.

Award of the Merritt H. Cash Prize.—Dr. Suiter read the report of the committee on prize essay. Three essays had been submitted in competition. The successful one was on auscultatory percussion and allied methods of physical diagnosis. It was by A. L. Benedict, of Buffalo.

Report of the Committee on By-laws.—Dr. H. D. Wey, of Elmira, read the report of the committee. The several recommendations made were acted upon separately. The first, providing for representation in the Society from the Elmira Reformatory and the State asylums for the insane, was opposed by Daniel Lewis, who could see no necessity for it. He could see, however, an advantage in making the presidents of the several county societies ex-officio delegates to the State Society, and offered an amendment providing for the same, which was adopted:

No one shall be admitted as delegate who is not a member of a county society.

The recommendation that the meetings be held the last Tuesday in January instead of the first Tuesday in February, was referred to the nominating committee, who should also report on the advisability of changing the place of meeting.

The Symptomatology of Cerebellar Disease. Report of Four Cases, with Specimens.—Dr. W. C. Krauss, of Buffalo, read this paper. It gave a comparison of the more recent results obtained by Luciana with those which had gone before, Flourens, Gall, etc. Luciana's results had decided for all time that complete extirpation of the cerebellum produced neither paralysis of mind, volition, sensation, motion. That it produced first, irritative phenomena; second, ataxic phenomena. The ataxic phenomena were due to three principal conditions: asthenia, atonia, astasia. The author had collected eighty-four cases in literature with autopsy, showing cerebellar disease, and compared the symptoms with those produced by experiments upon animals. The symptoms were headache, vomiting, vertigo, ataxia, asthenia, inclination to turn toward side of lesion, convulsions, and secondary lesions, as nuclear changes affecting the eyes, etc., tremor, death; negative symptoms were impairment of sexual desire, of mind reflexes, etc. Two of the cases of which specimens were shown had been reported before. The third specimen was from a case of cerebellar abscess affecting left lobe, following backward fall twice. The diagnosis was made during life, but too late for operative interference.

Dr. Krauss said the symptoms, in this and the other four cases of cerebellar disease seen by him, had been the classical ones. There had been no autopsy in the fourth case.

Abnormal Facial Development. A Study of Causes and Results.—Dr. Sumner Hayward, of Rochester, showed several silhouettes, illustrating normal and abnormal facial development, accounting for the latter by mouth breathing. Herbert Spencer was quoted on the law of harmonious development, to the effect that it depended upon growth and the influence of function. In normal or nasal breathing the mouth was fixed by the muscles, which caused the jaws to develop and assume the square form, the tongue exerted pressure against the roof of the mouth, giving it volume and breadth. In mouth breathing the jaw was dropped, the muscles thereto were not developed, the face assumed an elongated form, the mouth the appearance of the fish mouth, the palate narrow and apparently elevated. The author differed from those who attributed certain results to atmospheric pressure.

Thirty-nine Cases of Strangulated Hernia, and the Lesson Taught by them.—Dr. W. B. De Garmo, of New York, in an analysis of the 39 cases seen by him the past ten years, had found 26 in males, 13 in females; 28 inguinal, 8 femoral, 2 umbilical. In 22 there was reduction without operation. Three died, all cases seen after the tenth day. In nearly all the cases so-called taxis had failed in the hands of other physicians. Dr. De Garmo succeeded by a kind of traction or milking process, and strongly disapproved of ordinary ill-directed efforts, especially under anæsthesia.

Infants seldom required operation. Medicines and external applications were dangerous because their use encouraged delay. Rough handling was more dangerous than operation. Hot water most quickly determined whether resection was necessary on account of gangrene. Operate rather than attempt the reduction of a hernia actually strangulated twenty-four hours. Open the internal ring in every instance. Always draw the bowel down far enough to examine the point of actual constriction. It was not good practice to give cathartics after strangulation and return of suspicious vomiting.

Dr. Dallas, of New York, referred to a paper read by him before the Society two years ago, in which he described a method of taxis that had succeeded in, up to date, over fifty cases of strangulated hernia, in many of which other physicians had failed on numerous attempts with ordinary taxis.

Dr. Bristow, of Brooklyn, related some experience, and said he was convinced that if an operation had been done in the first instance in all cases of strangulated hernia, the results would have been better than by taxis.

Dr. De Garmo agreed essentially with Dr. Bristow. Operation was feared by many physicians, whereas it was very simple, all probably could do it with safety, at least with greater safety than they usually performed taxis.

The Prevention of Hernia after Laparotomy, with Exhibition of a Device for Relieving Strain upon the Abdomen.—Dr. Henry S. Durand, of Rochester, in this paper, stated some objections to methods in use for relieving strain upon the wound, and described a device first employed by him eight years ago. It consisted in attaching crêpe lisse with eyelets to the integument on each side of the abdominal wound, and drawing them toward each other by lacing. This took stress off of the intervening integument and, he thought, off of the divided edges to the full depth of the wound, allowing opportunity for formation of a firmer cicatrix.

Dr. Waldo thought proper suture would do away with the necessity for this device in most cases, but was glad to know it did not make pressure on the cicatrix.

Dr. Daniel Lewis had been accustomed to draw the edges of the wound together, in breast operations, by strips of gauze attached to the skin on each side by collodion, tying them in a knot over the wound, a dressing being beneath.

Dr. De Garmo and Fish also made a few remarks.

Inversion of the Appendix Vermiformis. — Dr. George M. Edebohls, of New York, in a paper with this title, stated objections to the two usual methods of disposing of the appendix stump—the first by simple ligation and excision, leaving cut mucous surface exposed in the peritoneal cavity; the second by pushing the ligated end in and stitching peritoneum over it—and advocated in their stead inversion into the cæcum, then covering the outer lumen by the peritoneal coat which had been previously stripped back. This treatment applied where the appendix was amputated, and also to the whole appendix when in other abdominal operations the healthy appendix came into view. He

could not say what became of the appendix thus inverted into the cæcum, nor did he care much, since, if it necrosed, it could only be discharged with the fæces.

Drs. McDonald, Fisk, and Clark offered objections to the procedure described, some of which Dr. Edebohls showed to be based on misconception.

Dr. Liell and Dr. Boldt thought inversion an admirable method of disposing of the stump in certain cases; while Dr. Currier expressed fear of exposing it to the influence of the fæces within the cæcum, and would like to know more of the after-result.

A New Method of Closing the Abdominal Wound after Cœliotomy.—Dr. Ralph Waldo, of New York, described a new method of closing the abdominal wound, the object of which was to further diminish the liability to hernia. In the diagram the walls were represented by three layers in which was the gap of the incision, one suture entering nearer the edge of the wound, passing down under the second line and out of the opposite side, at a point corresponding to point of entrance. A second suture entered more distant from the edge of the wound, passing down through the three lines or layers of the abdomen, and out on the other side. Dr. Waldo was positively opposed to buried sutures in the abdominal wound, because of the hiding of suppuration and burrowing of pus which sometimes formed.

Drs. Boldt and Currier believed it impossible always to prevent hernia.

Clinical Report Showing Tolerance of the Peritoneum and Nature's Kindness to the Surgeon.—Dr. Henry L. Elsner, of Syracuse, related the case of a patient who was operated upon by an expert gynecologist in New York, who removed the uterus with a fibroid and the ovaries. She suffered from a fistulous tract afterward and certain symptoms which it was difficult to explain, and it was proposed that laparotomy be again performed. This, however, was not done, and six months after the hysterectomy she discharged a large gauze pad per rectum. This had probably been overlooked by the nurse reporting all sponges and pads removed when she had counted one folded on itself as two.

Dr. Edebohls said a case had been reported in literature where a large pad had been left in and was subsequently passed at lower angle of the abdominal wound.

Dr. Boldt had within a year removed a fibroid of the uterus; the woman did well a while, then complained of griping pains, and after two months brought him a gauze pad which she had passed per rectum.

Report of Three Extra-uterine Pregnancies.—Dr. Arthur B. Breese, of Syracuse, reported the three cases. One showed probable injurious results from use of electricity, and all the undesirability of delayed operations.

Dr. von Ramdohr discussed the paper.

Double Pyosalpinx Evacuating through the Uterus; Curettage Followed by Pregnancy and Delivery of a Living Child at Term.—Dr. Edward N. Liell, of New York, reported the following case: Mrs. R. W—— was referred to me May 5, 1891. Gave a history as follows: Aged twenty-four, married; has suffered acutely since her confinement, two and a half months ago, although she had some trouble following a miscarriage three years previously. Temperature, 100⅘° F.

Examination proved the uterus to be anteverted, with considerable fixation; to the right and partly behind the uterus was an adherent mass the size of an ordinary lemon; a second irregular enlargement the size of a hen's egg was also felt to the left of the uterus; the left ovary was slightly enlarged, the right could not be mapped out. The vaginal examination was supplemented by that through the rectum, thus rendering the diagnosis more positive. The diagnosis of double pyosalpinx, the result evidently of puerperal septic infection, was made. Immediate abdominal section being refused, it was held in abeyance until such indications as might possibly make such performance imperative. Vaginal hot-water douches, sulphate of magnesia to produce watery stools, and turpentine stupes were resorted to. The daily u[illegible] of one grain of morphia, which she had been subjected to for over two months, was stopped, replacing it by teaspoonful doses of bromide. Temperature reduced on fourth day to 99⅘° F.

May 11th.—I was called in haste, the patient stating she had felt a sudden sharp pain in her right side, followed shortly thereafter by a sudden gush from the vagina of a purulent liquid. Examination showed complete collapse of the mass on her right side, as well as a decidedly purulent liquid oozing from the cervix.

A similar result occurred two days later on her left side, temperature falling to 98⅘° F. the following day. Patient's condition gradually improved in every respect from this time on. The need for abdominal section had passed decidedly, her condition being favorable to a final recovery. Curettage was refused at this time, but was resorted to in March, 1893, with excellent results for six weeks following its performance. Examination developed but slight tenderness on her right side, absolutely none on her left, being at the same time entirely free from pelvic pain for the first time in four years.

Next saw the patient again April 16, 1894; had not menstruated since February 12th, flow then scant. The question of possible pregnancy arose, but was strongly doubted at the time. Examination detected an enlargement of the right tube as well as an increase in size of the uterus. Further examination, a month subsequently, showed a normal pregnancy with a recurrence of her original tubal condition on right side. Quickening was felt as late as August 1st.

December 2d.—There was a discharge from the uterus similar in character to that of May, 1891.

She was confined on December 4th, aided by high forceps, because of uterine inertia supervening. Cyanosis accompanying was due to twisting of cord about child's neck.

As to which tube and ovary were the means, in part, of her conceiving, I am not in a position to state; from the fact, however, that six weeks subsequent to the curettage, and up to and during her pregnancy, the left tube and ovary were apparently in a normal condition, while the right enlarged and gave rise to much suffering later on, the left were evidently the favored ones.

The question of a pyometra in either an ordinary or bicornute uterus, or an ovarian abscess, or hydrosalpinx was brought up, but were differentiated from.

In concluding this interesting and instructive paper the doctor suggested that though an operation may be seemingly imperative, yet it may not, at times, be unwise to accept of temporary delay, being sensible of every indication presenting.

Treatment of Colles Fracture.—Dr. Nathan Jacobson, of Syracuse, in a paper on this subject, referred to the work of Moore, of Rochester, of Pilcher and others, and said that while he had occasionally seen uncomplicated fracture of the lower end of the radius, it was not the typical Colles fracture. In the latter the ulna was also involved, or entangled, as Dr. Moore had expressed it.

In treatment, Dr. Jacobson had found no splint necessary. There must be complete reduction, then simply apply a bandage and adhesive plaster. The forearm must be carried in a sling, the weight of the hand retaining the ulna in its replaced position. In Germany they applied a plaster splint, which would account for their bad results. The fault with treatment, however, was usually due to incomplete reduction rather than to splint appliances.

Ringed Eruptions; A Study in Differential Diagnosis.—Dr. George Thomas Jackson showed lantern slides of photographs, taken by Dr. Fox, of numerous cases of ringed eruptions pertaining to ringworm,

syphilis, psoriasis, ptyriasis, and other diseases, dwelling upon points of differential diagnosis.

Effects of an Occupation upon Vision.—Dr. Lucien Howe, of Buffalo, illustrated with lantern slides the manner in which astigmatism was produced in artists. Those engaged in this line were in the habit of stepping back from their work frequently and viewing it with pinched lids, which in the course of time caused a change in the form of the cornea.

Lantern-Slide Exhibition of Photo-micrographs, illustrating the Structure of Cancer and Some other Pathological Conditions was made by Dr. John A. Fordyce, of New York.

Exhibition of Lantern Slides of Leprosy, with Remarks.—Dr. P. A. Morrow, of New York, showed a number of lantern-slides of photos of lepers, mostly of those in the colony at the Sandwich Islands. They fully illustrated the various lesions of the anæsthetic and tubercular forms, also of mixed forms. Dr. Morrow considered leprosy as contagious, although in some instances those living in intimate relationship with lepers escaped the disease. The photo was shown of the convict inoculated successfully with leprosy, the only experiment of the kind on record.

Second Day, Wednesday, February 6th.

Dr. George W. Brush, of Brooklyn, offered the following :

Whereas, The proposed legislation limiting the legal age of consent in this State to eighteen years, instead of sixteen, is a measure calculated to limit the social evil with its attendant disease and physical as well as moral degradation ; therefore,

Resolved, That the proposed legislation meets with the cordial support and approval of the Medical Society of the State of New York. Adopted and referred to Committee on Legislation.

Committee to Enforce Law for Prevention of Blindness.—The President appointed on this committee—Drs. Lucien Howe, of Buffalo ; H. D. Noyes and D. B. St. John Roosa, of New York ; E. D. Stoddard, of Rochester ; and W. C. Wey, of Elmira.

The Brain of a Suicide with Two Pistol-shot Wounds.—This paper, by Professor B. G. Wilder, of Cornell University, was illustrated by the brain itself and by blackboard drawings. A preliminary account of this case was published in the *Journal of Nervous and Mental Diseases* for December, 1894, and copies were distributed. So far as can be inferred, the first ball entered the middle of the forehead, abraded the cortex of the mesial aspect of the left frontal lobe and lodged near the precommissure. The second entered the right temple and passed sinistro-dorso-caudad, traversing the right subfrontal gyre (Broca's), the insula, striatum, capsula, paracoele (lateral ventricle), callosum, corona, and left central (Rolandic) region. The natural presumption is against the probability that two bullet wounds of the brain could be self-inflicted, and hence in such cases the suspicion of homicide might arise. In this instance letters written by the deceased shortly before the act leave no doubt as to his suicidal intention. He was a dentist, living in Ithaca, and had bequeathed his brain to the University. It presents some fissural peculiarities which will be described hereafter.

A Decerebrized Frog.—Professor B. G. Wilder, of Cornell University, had brought with him a frog from which the cerebrum was removed on the 7th of December, two months ago. Since it was devised by Goltz the experiment is common in physiological laboratories, but Professor Wilder has been fortunate enough to keep one alive for more than eight months. As shown to some members of the Society the animal seems to lack consciousness and volition, but retains not only the reflexes and other functions dependent upon the myel and oblongata, but also the power of swimming, righting itself when turned over, and maintaining its balance upon a cylinder slowly rotated. Indeed, he did this not only when the rotation induced him to creep forward, but also when it was turned in the opposite direction. He takes no food voluntarily, but swallows what is put into the throat. Professor Wilder expressed the hope that representatives of medical journals would not speak of this as a brainless frog, as did some newspaper reporters when it was shown to the Association of Anatomists at Christmas.

Treatment of Puerperal Septicæmia in the Practice of a Country Practitioner.—Dr. John Mann, of Jericho, related two cases of puerperal septicæmia, treated successfully by curette, bichloride douche, and introduction of gauze. The treatment was surgical ; little reliance was to be placed on drugs.

Dr. F. W. Sears, of Syracuse, thought we must understand the different forms of surgical infection in order to treat puerperal sepsis successfully. In sapræmia, where there was retained and decomposing clots, etc., the symptoms of fever seldom began before the third day ; the temperature rose fast. Such cases were usually successfully treated by a single irrigation. In true infection there was injury, the fever began earlier, but rose gradually, the treatment had to be persisted in in order to prevent further infection. Here a single injection would never cure.

Dr. A. F. Currier, remarking upon saturation of the uterus with septic matter, expressed himself against extirpation of the organ. The patient's powers were already too severely taxed to withstand the additional shock of this major operation.

Dr. Frank S. Low, of Pulaski, had never lost a woman from puerperal septicæmia. He had acted on the motto that meddlesome midwifery was bad. He did not believe in irrigation of the uterus.

One gentleman said he used irrigation for ten days after labor in all cases of midwifery, while two others opposed meddling, believing that in this way infection would be avoided. One party even discarded vaseline or any oily application to the hand or forceps.

Dr. Wilder said that as a biologist he could see no use of the finger-nails except for opening a pocket-knife, and he thought it would be well if we could get rid of this excrescence of our scratching, fighting ancestors.

No Annual Dinner.—Owing to the destruction of the Delavan House the annual dinner could not take place, but the members were invited to a reception at the Albany Club by Dr. Fox.

Report of the Medical Examining Board.—Dr. Morris Lewi read the report. The total number coming up for examination was 536. Fifty-nine of the number had come before the homœopathic board, seven before the eclectic. Of the homœopathic, twenty-two per cent. had been rejected ; of the eclectic, fifty-seven per cent. ; of regular, thirty-three per cent. Most States recognized a license granted by this board on account of the high grade which it required.

The board thought that after 1897 none should be allowed to come up for preliminary examination for the study of medicine who had not completed a high-school course. The report with its recommendation was adopted.

Shall Insane Criminals be put to Death?—Dr. J. B. Ransom, of Dannemora, in this paper took strongly the ground that an irresponsible criminal should not be held to responsibility and be put to death. To his knowledge there were many inmates of our State prisons, some condemned to death, who were irresponsible, and who were so when sentenced. At autopsy on such persons he frequently found meningeal change and atrophic cerebral areas.

Dr. Ransom reviewed the medical evidence in the cases of Prendergast and Mrs. Halliday, showed pho-

tos, and gave these as striking instances of irresponsibility; yet Prendergast was submitted to judicial murder, and Mrs. Halliday escaped only because the governor appointed physicians to pass upon her sanity and they found her insane.

Dr. Ransom said the difficulty lay with expert testimony, and with the court in judging of responsibility. He believed the whole system should be changed as to the manner of obtaining expert testimony, and suggested that there should be a non-partisan board, say appointed by the governor with approval of the senate, which should hear expert testimony and report to the court. This would tend to rid us of the incompetency, venality, and sensationalism connected with medical expert testimony.

Dr. H. E. Allison, of the Matteawan Hospital, said the insane in the prisons were sent to the Matteawan Hospital, to be returned when cured. Of about two hundred persons in the State under life sentence, seventeen per cent. were in that hospital as insane. Many had been sentenced to death, but the sentence had been commuted by the governor to life imprisonment. At least four per cent were sent here from Europe. Prendergast, Mrs. Halliday, and their class, committed a criminal act by reason of their insanity, and it was manifestly wrong to hold them responsible.

Dr. Carlos F. McDonald thought punishment should not be inflicted upon the insane criminal. The methods of obtaining expert testimony were radically defective, for reasons clearly set forth by the speaker. The courts and lawyers held that one was responsible if he knew the consequences of his act and that it was wrong, whereas the medical profession, advancing, considered the question of responsibility to depend on health and disease. There was a general opinion that all insane were noisy and demonstrative. In reality, few were so. Again, there was a belief that the insanity plea was often successful, but he knew personally of only two instances where the sane had escaped punishment on this plea, and those adjudged insane were seldom discharged when sent to asylums instead of prison.

Dr. McDonald did not think the execution of a Prendergast or other insane person had a deterring influence on others of their kind who felt that they had a divine commission to murder. Such persons believed themselves healthy; they did not appreciate the insanity of their purpose.

Dr. Burt G. Wilder queried what was a normal brain, and said he had been on the still hunt for one among his friends and acquaintances for some time. What was wanted for comparison was more brains of persons of known intelligence, and he had the promise of a number such. He regretted that Guiteau's brain had been cut into pieces not larger than one's thumb, destroying its value as a study in form, size, etc.

Dr. W. J. Morton had been so disgusted with the degradation of justice permitted by present methods of bringing out expert testimony, that he had ceased to go to the courts as a witness. He hoped the Society would express an opinion upon the question raised in the paper.

Dr. E. D. Fisher thought many insane were deterred from criminal acts through fear of punishment.

It was moved to refer the suggestions in the paper to a special committee, to report at the next meeting, as to change in manner of obtaining expert testimony. The motion was adopted.

Dr. Phillips had good reason to believe that England was systematically sending its criminal insane to this country. He would like the committee to investigate that subject.

Some Suggestions Regarding Medical Examiners and Inquests in Cases of Death by Violence.—Dr. S. L. Dawes, of Saugerties, in this paper presented the outline of a proposed bill to replace the present coroner system in the State, excepting New York City. It was referred to the Committee on Legislation.

Recreations in Modern Medical Science, No. 6.—Dr. John H. Doughty, of Matteawan, aroused the Society by a kind of poetical effusion with this title.

The Cure of Cancer.—When the lymph-nodes are involved. Dr. B. F. Curtis read this paper, which will appear later. It was discussed by Drs. Samuel Lloyd and Van Derveer.

Report of Committee on President's Address.—Dr. A. W. Suiter read the report. It recommended a change of time of meeting to the last Tuesday in January; that the question of the disposition of executive business be considered by a special committee to report at the next meeting; that the secretary be given authority to transfer volumes received in exchange to the medical department of the State library for more convenient reference. On motion of Dr. W. C. Wey the report was adopted.

State Examiners Recommended.—The committee recommended Eugene C. Beach, J. P. Creveling, A. W. Suiter, E. B. Angel. The report was accepted and adopted.

Report of Committee on Legislation.—The members of the committee recommended its successors to introduce a bill to secure proper penalty for the illegal practice of medicine. The report was adopted.

The President appointed as committee on recommendations contained in Dr. Ransom's paper, Drs. Ransom, McDonald, H. E. Allison, Ward, and E. D. Fisher.

State Care of New York's and Kings County's Insane Recommended.—Dr. Carlos F. McDonald offered the following, which was adopted without discussion:

Whereas, Recent investigation of the condition and management of the asylums for the insane in the City of New York has clearly shown that the system of county care, under which these institutions are now conducted, is a failure as regards its humane and economic aspects;

Whereas the same is substantially true of the institutions for the dependent insane in the county of Kings;

Resolved (essentially), That the Committee on Legislation urge legislation extending the system of State care to these counties also.

Anniversary Address by the President.—Dr. George Henry Fox chose for the subject of his address, "Credulity and Scepticism in Modern Medicine." The majority, including most of the younger members of the profession, were always ready to adopt that which was new, while the conservatives or fogies (who by the way, were not always old), were inclined to leave things as they were and do as their fathers had done before them. The spirit of the age in which we embark is carrying us all to the same goal and with the same speed. No man can escape the influence of the prevailing thought of his generation. All, whether leaders or followers, could not do otherwise than advance. Credulity existed as strongly to-day as in the days of witchcraft, and its results might appear as serious to those who should come after us. The credulity of patients was sometimes amusing, but also often lamentable. The physician often had a feeling of humiliation when he found reputation and learning wholly unappreciated by the patient. It was credulity which led the public to place faith in the assertions of charlatans, and which opposed an obstacle to higher medical education. Yet the high position of the profession to-day was largely due to recognition of the fact by the public that learning and skill were the bases of successful medicine. As long as the people liked to be humbugged there would be unscrupulous charlatans, and some physicians, to do the operation.

Dr. Fox lamented the fact that over-credulity on the part of physicians had caused the Pharmacopœia to be replaced to great extent by proprietary medicines of enterprising manufacturers, and to the filling of medical journals with articles which never would have been pub-

lished had they been held back six months. Medical journals, like preachers, often presented one side of a subject with such zeal as to make us wish to hear the other side from an advocate equally earnest

Therapeutic scepticism was commended to the younger members of the profession. Both physicians and public were to blame for the demand on the part of the latter for drugs, and their inattention to hygienic advice.

Dr. Suiter offered a resolution, which was passed, directing the Committee on By-laws to investigate and report on more strict limitation of admission of delegates from incorporated societies.

The Secretary was instructed to notify the presidents of the county societies of the increase in the number of senatorial districts, which would under the law admit more delegates to this Society.

The Surgical Treatment of Empyema of the Antrum.—Dr. Samuel Lloyd, of New York, read the paper. After referring to diagnosis, based on discharge of pus, swelling of cheek, redness of gums, absence of translucency in the affected antrum with electric light in the mouth, etc., he passed to the surgical treatment, which consisted in opening into the antrum, cleansing it and draining. Among methods of entering the antrum was that by extraction of a tooth and entering through the alveola, to which a principal objection was the small size of the opening. A larger opening was permitted under the cheek; another approach was through the turbinated bone. The suggestion to enter through the hard palate had not been acted upon.

Dr. W. C. Phillips would object to the use of peroxide of hydrogen, unless simply for diagnostic purposes, since if pus were present it would produce a clot which could not find escape through the natural opening into the nose. Except in chronic pus cases, he would not approve of an artificial opening.

Treatment of Blenorrhœa of the New-born.—Dr. W. F. Mittendorf, of New York, in this paper urged the necessity of attention to blenorrhœa of the new-born, since it was the chief cause of blindness. Prevention was by antiseptic midwifery and use of Credé's method, introduction into the eyes of the child of two or three drops of solution of nitric acid, one grain to the ounce. The disease having developed, irrigate the eye every five minutes during active inflammation, then keep lids from becoming glued together by very frequently introducing ointment composed of vaseline nine parts, borax one part. Use solution of nitrate of silver as soon as the secretion becomes purulent.

The Gauge of the Normal Urethra in Relation to the Permanent Cure of Urethral Stricture.—Dr. Charles Stover, of Amsterdam, in this paper referred to the pioneer work of Otis in determining normal urethral measurements, also to the work of White, and by clinical experience sustained the view that internal measurements should be made as giving more exact indications for cure than was furnished by estimates based alone upon the circumference of the penis.

Injuries and Hemorrhages of the Urinary Tract; Treatment and Cases.—Dr. John A. Heatley, of Schenectady, read on this subject. Little could be done by way of medicinal treatment in hemorrhage further than to enforce rest and apply cold.

Would Have Representation in the Board of Regents.—Dr. A. W. Suiter offered a resolution, which was adopted, respectfully urging the Senate and Assembly to appoint a member of this Society on the Board of Regents of the University of the State of New York.

Electricity in Medicine From a Modern Standpoint.—In the absence of other authors of papers on this subject, Dr. W. J. Morton made some introductory remarks, and read two papers, one upon "Electro-Physiology," and another upon "Electro-Therapeutics." Physicians must acquaint themselves with electrical engineering, which had made such great strides of recent years, if they would understand electro-physiology and electro-therapeutics. In relation to electro-physiology the author pointed to the existence of animal electricity, to the electrical influence produced by function or irritation of muscular, nervous, secretory, and other tissues, and said, however, that such electricity was no more life than was heat attending the same phenomena. The physiological reactions produced by the current might be classed as protoplasmic reaction, nerve reaction, and muscle reaction. Interruptions of current from 2,500 to 5,000 per second produced the maximum contractile effect, while 10,000 or more only influenced nutritive changes. Alternations of 100,000 per second produced simply metabolic influence, while the same voltage and diminished alternations would produce death. No satisfactory explanation had yet been given for this phenomenon. The author thought we had here a suggestion for future therapeutics in rheumatism, gout, melancholia, etc., of possible extreme value.

Some of his conclusions on electro-therapeutics were: 1. Electro-therapeutics in a biological sense is the transformation, by the law of conservation of energies, of electric energy into the energy peculiar to the vital cells. 2. Electricity in medicine must be regarded not as an identity like a drug, but as having a variety of properties, each of which may be employed singly or combined. As to the galvanic current, strong currents depressed nutrition of tissues, produced structural changes and physiological atrophy (twenty to one hundred milliampères). Mild currents stimulated nutrition and produced physiological hypertrophy (one to eight milliampères). In inflammations he was decidedly of opinion that the negative pole should be used. Strong currents in neuritis, etc., enfeebled and did harm.

The author had obtained some brilliant results from metallic electrolysis, by which the copper or zinc electrode underwent decomposition and entered the diseased tissues under treatment and in contact with them. This method was of value in causing dissolution of trachoma, in chronic nasal catarrh, even in urethritis, etc. Dr. Morton had positive evidence of the influence of galvanism on uterine fibroids.

The paper was discussed by Drs. W. E. Ford, W. C. Phillips, Frank S. Low, and Burt G. Wilder.

The members and guests were invited to attend a reception at 9 P.M., by the President, at the Albany Club rooms.

Election of Officers.—*President*, Dr. Roswell Park, of Buffalo; *Vice-President*, Dr. Madden, of Brooklyn; *Secretary*, Dr. F. C. Curtis, of Albany; *Treasurer*, Dr. Charles H. Porter, of Albany.

A Medical Philanthropist.—We have received intelligence of the death of Dr. Tourasse, of *Saint-Maur-les-Fossés*, where the inexhaustible philanthropy of our *confrère* had grown into a proverb. He treated the indigent, for the most part, and would never accept a fee: a method of carrying on a practice sure to bring in plenty of patients, and never a lawsuit. The following anecdote is a favorite with Dr. Tourasse's friends: "A few years ago a workman in the Gravelle iron-works had his lower extremities crushed beneath a mass of metal. Our doctor having successfully amputated one of the damaged limbs, gave the unfortunate man twenty francs to buy himself an artificial leg; but the following day, when he paid his customary visit, instead of finding his patient with a wooden stump, the wretch was completely drunk, having spent every farthing in liquor. Without saying a word Dr. Tourasse immediately took train to Paris, purchased an apparatus, and returned in order to apply it with his own hands. M. Tourasse died a pauper. The Municipal Council of *Saint-Maur*, in recognition of the noble character of the deceased, have accorded a 'gratuitous concession' to his remains!"—*Journal de Médecine.*

NEW YORK ACADEMY OF MEDICINE.

SECTION ON GENERAL SURGERY.

Stated Meeting January 14, 1895.

B. FARQUHAR CURTIS, M.D., CHAIRMAN.

Exstrophy of the Bladder.—DR. ROBERT ABBE presented three cases of exstrophy of the bladder. The treatment of this condition, he said, was rather trying, but he thought the technique could be improved and better results obtained. One of the three children shown illustrated a minor degree of the malformation. Another had complete exstrophy, the third had been markedly improved by the treatment, which was still being carried out. In the more marked case the dorsum of the penis was split, the symphysis was separated to the extent of admitting three fingers side by side, the anterior abdominal walls were absent to above the umbilicus, the posterior wall of the bladder and lower end of the ureters presented. In the case in which treatment had been begun he had adopted the method of Trendelenburg, separating the sacro-iliac synchondroses and applying pressure so as to bring the pubic bones nearer to each other and thereby diminish the opening preparatory to a plastic operation anteriorly. Dr. Abbe could see no reason why, with extensive freshening of the skin at the sides and inversion, and perhaps the use of heavy mattress quilting suture, the sides of the opening could not be brought together.

Reproduction of the Entire Tibia after Necrosis.—DR. J. E. H. NICHOLS presented a girl, over twelve years of age, whom he had treated when seven years of age for phlegmonous cellulitis following a blow upon the tibia. A pus cavity existed when he saw her, which he opened. But caries went on until the entire tibia was shelled out. The child was kept in bed fourteen months, at the end of which time the tibia had reproduced itself from the periosteum and she could walk perfectly.

A Useful Arm without Bony Connection at the Shoulder.—DR. BLAKE presented a man who had been operated upon when two years of age for complete removal of the shaft of the humerus. He was now twenty-two years of age, had a well-developed forearm; the upper arm was short, little of the shaft was present, the lower epiphyses were apparently of normal size and form, there was little if any of the upper end of the humerus, and the lower end was separated from the shoulder by a gap of about an inch. This permitted of voluntary and passive flail motion. Yet the muscular development and control was such that the man had complete use of his arm for all sorts of work, laborious or otherwise.

Cases of Excision of the Knee-joint, with Remarks on the Indications for Operation.—DR. ARPAD G. GERSTER presented three adult patients, and had expected a fourth to be present, on whom he had excised the knee-joint for tuberculosis within the past six weeks. He had kept records of sixty-nine cases so operated upon during the last seventeen years for tuberculosis. The cases presented were intended as a text in speaking of the indications for excision in this disease, of the operative treatment, the after-treatment, and the results. As long as there was progressive tuberculosis present in such cases, and absence of bony anchylosis, the patients remained invalids and suffered more or less with almost every jar. They had to go about with a cumbersome apparatus, and never stepped over a curbing without fear of provoking pain and injury which might lay them up for weeks. Whether rich or poor, their lives were miserable and wretched. Of the large number of cases operated upon by him, in not one had he found bony anchylosis.

The point which Dr. Gerster wished to particularly emphasize was the fact that the proper treatment of these old cases of tuberculosis of the knee was not orthopedic, but operative. There was no doubt on that point in his mind. All the cases shown had followed the rule, suffering little pain after excision, being able to sit up at the end of a week, and going about on crutches by the end of five weeks. They would soon have rigid bony anchylosis, and become useful members of society, free from pain and able to earn their living the remainder of their lives.

Speaking of the pathology, Dr. Gerster divided the cases into those of incipient tuberculosis of the knee-joint, and those in which the disease had advanced further, destroying the cartilaginous surfaces and involving the bone. In the latter class there were usually a number of cicatrices from old abscesses and sinuses, and new sinuses continued to form. In another form the disease commenced in the synovial membrane, and when advance caused peri-articular deposits, but the bone might not be involved. They were the cases of cold abscess which the surgeon was liable to open and add another form of suppurative action. It was a form of mixed tubercular infection frequently seen in hospitals twenty years ago, but seldom seen at present. As long as the disease was limited to the joint, excision was the proper treatment, removing the diseased tissue down to healthy bony surfaces, placing these in apposition, applying a splint, and thus securing bony anchylosis and complete cure. It was necessary to search for every pocket of pus, and remove all pyogenic membrane. If the knee were honeycombed with diffuse suppuration he advised against excision.

Infection following the operation was very rare when the Esmarch constrictor was used to cut off the circulation while operating. Dr. Gerster had lost no cases from the operation itself, and only two from distant tuberculosis, which may have been induced by manipulations during excision.

There were some cases of acute tuberculosis of the knee-joint which it was difficult to distinguish from rheumatism. The fever, however, was remittent, and the characteristic course of acute rheumatism was lacking. In operating Dr. Gerster made a transverse incision above the patella, extirpated this, sawed off the epiphyseal ends of the bones, giving attention to the proper plane. The inner side of the femur should be left a little longer than the outer in view of the natural position being that of moderate knock-knee. He did not approve of removing the constrictor before ligating the vessels. For convenience he inserted a nail into the ends of the bones. A veneer splint, not plaster, was used. Consolidation had failed to take place in only one of his cases. This patient could walk comfortably with a light support.

Discussion on the several cases presented was then called for. The CHAIRMAN (Dr. Curtis) inquired whether any of the members had had experience with the treatment of exstrophy of the bladder, or rather of the separation of the pubes which existed in that condition, by keeping the child lying on its back in a trough, without division of the sacral ligaments; or, on the same principle, by applying a rubber bandage around the pelvis.

DR. W. W. VAN ARSDALE queried whether extension had been practired in the case of non-reproduction of the shaft of the humerus, and said that even where periosteum had not been destroyed it was necessary to keep up extension in order to avoid shortening, and even to secure reproduction of bone. But with all precautions there was some shortening in about fifty per cent. of the cases of acute osteo-myelitis in children, and in some instances there was entire failure to reproduce bone.

DR. A. M. PHELPS made some remarks upon excision of the knee. Clinical experience had demonstrated that under the eighteenth year of age cases did not do so well if treated by excision. Where sinuses and abscesses existed one should open into the joint, and decide at that time whether excision should be done.

Old cases of constantly relapsing tubercular disease with fibrous anchylosis of the knee were, in his opinion, suitable for excision. By rapid operative work, shortening the duration of anæsthesia, and avoiding loss of blood the mortality-rate had been reduced to about three per cent. He performed Fenwick's operation, and had succeeded in completing it in fourteen and even in ten minutes from the time of the first incision to the last bandage. The bones were cut wedge-shape so as to lock into each other, thus preventing slipping by, without the use of nails. He had operated in sixty-eight cases. One patient had died while under ether; another of sarcoma, showing that the diagnosis of tuberculosis in that instance was a mistake; two or more died, after a year or so, of tuberculosis.

Dr. Dawbarn suggested the use of the coarse file where the plane of the sawed bones was not quite right.

The Chairman had not seen much loss of blood from the open method, and where hemorrhage had been considerable it must have been due to some abnormal condition. Nor was there greater danger of infectious matter entering the circulation than where the vessels were ligated before removal of the rubber bandage. He had used nails for the same reason Dr. Gerster had given, but recently he had had a case showing that they might be absolutely necessary in order to prevent separation by muscular spasm while redressing the limb.

Dr. Kammerer said that while in this country purely synovial cases were frequent, he had never seen an instance abroad in which a tubercular focus had not been found in the bones of the joint.

Dr. Gerster expressed surprise that Dr. Phelps was able to do Fenwick's operation in fourteen minutes, and, presumably, also clean out all foci of infection, as it was necessary to do in order to obtain a successful result. As to the open method, he had had hemorrhage from it, and had seen hemorrhage in the hands of Dr. Sands and others. The constrictor should not be applied too tight, lest a deluge of blood should follow its removal because of vasomotor paresis.

A Subgluteal Triangle and its Surgical Importance.—Dr. Ramon Guiteras read the paper and demonstrated the triangle by diagram and on the cadaver. The apex of the triangle was below at the intersection of the biceps, the gluteus maximus, and the vastus externus. Along the inner side was the long head of the biceps, above was the pyriformis, at the outside perhaps the short head of the biceps and the gluteus maximus. Within it were the great sciatic nerve, a little to the inner border; the sciatic and pudic arteries; two or three bursæ. The surgical importance of the space related chiefly to stretching the sciatic nerve, which was done little at present except for relief of pain, etc., in leprosy. There might be aneurism or hemorrhage of the sciatic or pudic artery; rarely pus from Pott's disease took this course; hernia of the pelvic viscera was likewise rare; inflammation of the bursæ might require surgical interference; the triangle bore important surgical relations to the hip-joint.

Dr. Woolsey thought the triangle had really four sides, although two formed nearly a straight line externally. The short head of the biceps did not always come up to the gluteus maximus. The fold of the nates had little to do with the border of the gluteus maximus, but was due to extension of the limb. One should bear in mind the possible bifurcation of the sciatic nerve. The gluteal artery, which was above the pyriformis, was more often the seat of aneurism than the sciatic artery which lay in the triangle. In either case the aneurism was hard to treat surgically because of the shortness of the trunk. The internal pudic could be pressed against the pubis. Abscess here was not likely to be that of hip-joint disease, but he had seen it from sacro-iliac disease, which he believed was more common than was generally supposed.

Dr. Dawbarn still believed in stretching the sciatic nerve for obstinate sciatica. He had never seen a man able to break the nerve by pulling upon it. The traction should be upon the proximal end, and should be equal to fifty pounds. He could tell at once in cutting down upon it which of the two muscles, the gluteus maximus or the biceps, he had struck, by observing the direction of the fibres; if toward the fibula, he was a little too low; if toward the tuber ischii, a little too high.

Dr. McGrath thought there was every reason for calling this region a triangle, which it was in fact, and by so designating it its importance was much more firmly impressed upon the minds of students. He had seen sarcoma operated upon in this region in one case.

Modified Murphy's Button.—Dr. Lilienthal showed a modified Murphy's button which he had made with a view to preventing it from falling back into the stomach in gastro-intestinal anastomosis. The stomach half was made larger than the intestinal half or section. He had not yet had occasion to employ it.

The Chairman suggested what appeared to be a fatal objection to the change, namely, that if the button at present in use were made larger at one end it would not pass through the intestine, and if made smaller it would not establish a sufficiently large opening.

Election of Officers.—Dr. B. F. Curtis was re-elected Chairman, and Dr. Royal Whitman, Secretary.

SECTION ON GENERAL MEDICINE.

Stated Meeting, January 15, 1895.

W. H. Porter, M.D., Chairman.

The Pathology of Appendicitis.—Dr. Robert T. Morris opened the discussion upon the above subject, and exhibited a large number of specimens to illustrate the various conditions of the appendix in its pathological changes. He said the first phenomenon in appendicitis was the formation of an infectious atrium, which might be excited by concretions, twisting, injury of the mucosa, traumatism from the contracting uterus in childbirth, etc. When the mucosa had been broken the bacteria which existed within the lumen increased rapidly and their toxins produced a series of secondary phenomena. First, was a serous exudate and the stimulation of Auerbach's plexus. The result of the exudation was compression of the mucosa and inner coats, causing them to swell and become compressed between the outer coats and the peritoneum. The stimulation of the branches of Auerbach's plexus caused spasms of the muscular coats of the intestines, thence of the abdominal walls. Through sympathetic stimulation the heart contracted rapidly, the arterial coats were stimulated, and through stimulation of Auerbach's plexus the clonic contraction of the appendix continued. The two mechanical factors were the compression from the exudate and the muscular spasm closing down upon this inner tube. The result of this compression was, first, the cutting off of the lymph, then the compression of the capillaries, and as the appendix had but one artery collateral circulation was impossible and the swollen organ projected like a peninsula. Thus the leucocytes could not gain free access to the bacteria, and the latter developed and destroyed the appendix to various degrees. When the small arteries were occluded and the nourishment was shut off, the infection was generally mixed and the streptococcus took the lead.

Foreign Bodies in the Appendix.—In discussing the subject Dr. A. M. Phelps said that he was much interested in the description of the blood-supply of the appendix, and the idea that the etiology was something that developed in the appendix and not something that got into it; yet he had seen a case where the appendix was removed and on examination he found a pin within the portion removed.

Conservative Treatment.—Dr. Thomas H. Manley said that he considered the pathology of appendicitis still a mystery, and the subject was to be regarded from the stand-points of constitutional and local changes. The question of local changes had been well sifted, and if this were all that was to be considered, it was a surgical disease. It had been his impression that acute cases could be controlled by vigorous treatment, and that surgical interference was necessary only in very serious cases. The question arose, Was not this a local manifestation of a general condition; was it not tubercular when not traumatic; was it not a latent type of syphilis; a local germ with a local action, brought on by certain conditions of nutrition? Dr. Manley said that he had treated five cases with mercurials during the past year and all had recovered. He had found the conservative treatment of appendicitis the most successful. He cited two cases of appendicitis from traumatism; one in a woman whose appendix was bruised in childbirth, the other in a lad who had been struck with great violence.

Appendicitis a Simple Inflammation.—Dr. L. T. Bishop said that the pathology of appendicitis seemed a simple matter when considered on the same basis as an inflammation in any other part of the body. There was the small canal, lined with a mucous membrane and covered by a serous coat, in which there was inflammation. The product of that inflammation might vary the same as in similar structures in any other part of the body, as, for example, the antrum of Highmore. If there were bacteria present, there would be infection upon interruption of continuity of the part, or upon irritation causing favorable conditions for their development. The rest of the pathology followed naturally, the suppurative inflammation extending to the serous coat, and peritonitis resulting.

Rheumatism and Gout as Factors in Appendicitis.—Dr. S. H. Dessau said that he wished to mention also the effect of rheumatism and gout in the pathology of appendicitis. These affections had a great influence on the history of many other diseases, and it seemed quite probable that they exerted no small influence in appendicitis. It seemed quite evident that appendicitis was much more prevalent now than formerly, and there must be some reason for it. He thought that Dr. Manley had struck the right method in conservative treatment. In his practice he had for six years used calomel in appendicitis with good results. It had the desired effect upon the inflammation, and also kept the bowels in favorable condition. The patient was kept entirely at rest and given one-tenth of a grain of calomel every hour for seven or eight hours, and then the dose was repeated every two hours.

Does not Favor Conservative Treatment.—Dr. A. M. Phelps said that if he had an abscess within his body he would not expect mercury to have much effect on it. He did not believe that germ-life began by destroying the mucous membranes. There must be a lesion. It was impossible to tell when there was going to be a suppuration, and the operation should be done at once. He watched the case, and when there was chill and rapid rise in temperature, he operated. There was no great danger if the operation were performed in time, and the mortality ought not to be more than two per cent. A vast majority of cases went on to abscess, and if not operated upon many of them relapsed. If he got a third relapse he always operated.

In conclusion, Dr. Morris said that concretions were very common, but bacteria was the important factor, while concretions might pave the way. Many of his patients had developed appendicitis after injuries. He thought the appendix became displaced, or dislodged and twisted, and the twist caused injury and dammed the mucus. He had found dammed mucus behind the twist without infection. As to the colon bacillus, this was found all over the body at times, but it belonged during life in the colon. When anything dead was about, the saprophytes and colon bacilli seemed to marry and go on an excursion hand in hand. He believed it was better to isolate the infected part, which meant operation, but if a diagnosis could not be made, no operation should be performed.

Election of Officers.—Dr. William H. Porter was re-elected Chairman, and Dr. W. Le Boutillier, Secretary.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Annual Meeting, January 21, 1895.

S. B. Wylie McLeod, M.D., President, in the Chair.

Election of Officers.—The following officers were elected: *President*, Dr. S. B. W. McLeod; *Vice-President*, Dr. A. D. Ruggles; *Recording Secretary*, Dr. P. B. Porter; *Corresponding and Statistical Secretary*, Dr. N. G. Bozeman; *Treasurer*, Dr. J. H. Hinton; *Member of Executive Committee*, Dr. T. H. Burchard.

Treasurer's Report.—The annual report of the Treasurer, Dr. Hinton, showed receipts for the year to the amount of $1,931, and disbursements to the amount of $1,765. The balance in the treasury was $166. The cost of the refreshments had been $293; rent, $225.

Report of the Corresponding and Statistical Secretary.—Dr. Van Arsdale's report showed a membership at the commencement of the year of 951, of which number 50 had been lost by removal, death, and other causes; one member had been expelled. Adding to the list the new members, the present number was 1,006.

Report of the Committee on Public Health.—Dr. T. H. Manley presented the report. While little that was new had transpired during the year to which further attention need be called, he said the present year promised a new epoch in New York. He referred to the proposed change in the Police Department, with the probability that the number of surgeons would be reduced; to the bill substituting medical examiners for coroners; and read the resolution adopted at the Academy of Medicine recommending the burning of garbage. On motion, the Association endorsed these resolutions.

The thanks of the Association were tendered the retiring Statistical and Corresponding Secretary, Dr. W. W. Van Arsdale, who had on account of other duties declined a renomination. The usual collation was then served.

The International Congress for the Treatment and Protection of Infancy will be held next year in Florence, and the organizing committee there are already receiving intimations from the physicians and surgeons of other nationalities signifying their intention to take part in the proceedings. Austria will be strongly represented, and communications are announced from her delegates on Children's Hospitals, Deaf-mutes, Blind and Idiot Children, Hospitals and Asylums for the Scrofulous and Rachitic, Correctional Establishments, Foundling Hospitals, Kindergarten, and Orphanages. The Vienna committee from which these contributions emanate includes the well-known names of Professor Wiederhofer, Count Falkenhayn, Baron Springer, Geheimrath Dr. Kusy, Councillor Theimer, Dr. Gnadinger, and Professor Monti.

Recrudescence of Cholera.—Nearly two hundred soldiers of the Prussian Army in garrison in a town of Silesia were taken ill not long since with symptoms of cholera. One of the government bacteriologists has been sent to determine the exact nature of the disease, whether genuine cholera or acute diarrhœa.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

CYCLING AND HEART DISEASE—PATHOLOGICAL SOCIETY'S EXHIBITS—COMING DISCUSSION ON PNEUMOCOCCI AND IMMUNITY—CLINICAL SOCIETY—THREE RARE ABDOMINAL SECTIONS AND RECOVERIES—LOCULATED EMPYEMA—THE COMMITTEE ON ANTITOXIN.

London, January 19, 1895.

The effect of cycling on the health is a subject of interest to a large section of the public, and wheelmen who do not go in for racing or record-breaking are unanimous on the benefit of this mode of exercise. There have, however, always been misgivings as to the effect on the circulating organs. These Sir B. W. Richardson, who is himself a veteran wheelman, endeavored to set at rest at the Medical Society, on Monday last, in a paper on "Cycling and Heart Disease," in which he discussed the effect of this exercise at the time, and such after-effects as may be met with in the consulting-room. He found that the immediate effect was to raise the pulse more than any form of exercise, as much as from 65 or 75 to 200, and though this fell somewhat after a time, a very high rate continued as long as the exercise was kept up; yet he had never seen a rider embarrassed by faintness, breathlessness, angina, or vertigo so as to be obliged to dismount, but he had known a man who could climb a hill on his machine though he could not go upstairs without palpitation. He had known cases in which after a number of years of cycling there was some cardiac disease. On the other hand, he had seen benefit from the exercise in varicose veins, fatty degeneration, and anæmia. Cycling, then, may benefit a feeble circulation if the arteries are sound, and it would seem a safer exercise than Hirtl's hill climbing. Three things were pointed out as most injurious, viz., straining to climb hills or to meet head winds; excessive fatigue; alcoholic stimulants and the omission of light, appropriate, frequently repeated foods.

Some interesting observations were made in discussing this paper, and there seemed a concurrence of opinion in favor of moderate exercise on a tricycle even when the heart is diseased. This, too, was held to be the best form of exercise that could be taken as a therapeutical measure in cardiac disease. On Tuesday last, (15th), the Pathological Society held a meeting, and many interesting specimens were exhibited, including five brains from insane patients; serous pachymeningitis with atrophy of some of the cerebral convolutions from a syphilitic child, aged nineteen months, and some slides from two cases of mammary cancer, which at one end presented the appearance of so-called "duct-cancer." This exhibit led to some conversation on the use of this term, from which I gather that pathologists might be more precise in the use of terms—not a few of which are too often applied by different observers in by no means the same sense.

It was announced that on February 5th Dr. Washbourn will open a discussion on "Pneumococci in Relation to Immunity."

At the last meeting of the Clinical Society of London, held on the 11th inst., Mr. A. W. Mayo Robson related three cases of abdominal section for unusual conditions, all followed by recovery. The first case was one of tubercular abscess of the liver, treated by incision, rubbing in iodoform, and drainage. The patient, whose illness had extended over twelve months, and who was reduced to an extreme degree of weakness, has completely recovered his health. The case, as well as the treatment adopted, was certainly uncommon. The second case was one of volvulus and strangulation of the omentum following on the reduction of a large inguinal hernia. Peritonitis led to the suspicion of reduction *en masse*. Abdominal section revealed the whole of the omentum in a state of deep congestion verging on gangrene, connected by two twisted cords with the stomach above and the left inguinal cord below. The case was unique. The third case was one of traumatic intra-peritoneal hemorrhage without external wound, in which the patient was in so serious a condition that exploration to reveal the actual site of the hemorrhage would probably have led to death on the table; incision, washing out with hot saline solution, and drainage arrested the bleeding and recovery ensued.

The President, Mr. Kulke, said that in the post-mortem room he had never met with a large, solitary, caseating tubercular mass in the liver unaccompanied by tubercular manifestations elsewhere. He had also never seen or read of such rotation of the omentum as was present in the author's second case. There was scarcely any viscus, except the brain, in which rotation had not been observed, and it was frequently observed in connection with floating kidney with long stalk, and wandering spleen, and he mentioned several cases.

Mr. Croft mentioned that on one occasion he had removed a spleen in order to arrest hemorrhage from it, the abdomen at the time being full of blood. The patient was apparently on the point of dying of collapse, but lived for some hours. He thought it was a mistake to delay ascertaining the exact source of hemorrhage. If it proceeded from such an organ as the spleen, the chances were slight of its spontaneously ceasing. In all such cases an exploratory operation should be performed at the earliest possible moment.

Mr. Battle said as tubercle bacilli were found in the abscess contents, but nothing like ray fungus, and there were no signs of rupture of a viscus, it was quite impossible to say where the hemorrhage came from. He had had at St. Thomas's Hospital a boy who fell on his face while playing at leap-frog, and was brought in with symptoms of intra-peritoneal hemorrhage. There was intense shock, and a dull area on the left side extending as far as the left linea semilunaris. He had been vomiting, and there was still some vomiting, but no rigidity of the abdominal muscles. The dulness in the abdomen gradually extended until it reached the right linea semilunaris. The boy recovered. He had no idea where the blood came from, but he thought it might be from a torn mesentery. He raised the question as to what symptoms are to be held to justify laparotomy forthwith. Would tympanites? He thought it would.

Mr. Mayo Robson, in reply to other questions, said he did not think there could be any doubt as to the tubercular nature of the disease in the first case. Tubercle bacilli were found in the abscess-contents, but nothing like ray fungus. The patient was ultimately discharged as cured, and there was no trace of disease anywhere. With regard to the second case, he thought it was very difficult to account for the rotation. If in his third case he had tried to find the source of the bleeding, he felt sure he would have lost his patient; even flushing the abdomen was sometimes followed by shock.

Mr. Frederick Eve related a case of acute intestinal obstruction by gall-stone for which he did laparatomy and removed the stone, recovery following. After the operation it was elicited that eighteen years previously the patient had been subject to severe attacks of pain in the epigastrium, sometimes accompanied by vomiting. For seven or eight years he was never entirely free from pain, but about once a week had a severe attack. Ultimately the pain and attacks of vomiting ceased quite suddenly. He had never passed a gall-stone. This trouble may be referred to the presence of a biliary calculus in the gall-bladder, and the sudden cessation to its passage into the duodenum; so that it may be inferred that the calculus had occupied the intestine for some ten years—a circumstance not

without precedent. Mr. Eve offered the following suggestions: 1. When a diagnosis is possible expectant treatment should be tried, as one-third of the cases of marked obstruction from gall-stone recover without operation. 2. Operative interference should not be long delayed, as the patients are nearly all aged, the mean age being sixty-four years. 3. After opening the abdomen the calculus should, if possible, be forced through the ileo-cæcal valve. 4. If the calculus be immovable, or at a distance from the valve, and the intestine be healthy, the stone should be excised. 5. When the intestine is inflamed, and the stone immovable and adherent to it, an attempt should be made to break the calculus up with needles. This failing, it should be extracted, the intestine fixed to the abdominal wall near the wound, and surrounded with iodoform gauze. 6. In only one case out of twenty-seven was it found necessary to resect the intestine on account of ulceration. These conclusions met with approval, but serious doubts were expressed as to the propriety of needling.

Mr. W. J. Browne related a case of empyema attended with unusual difficulty of diagnosis.

The President announced that the following gentlemen had been appointed members of the committee to inquire into and report upon the antitoxin treatment of diphtheria: Messrs. Couper, Goodall, Thorne Thorne, Gee, S. Martin, H. D. Hawkins, Hale, White, Washbourn, and Pasteur. Sir J. Lister had been invited, but was unable to join.

New Instruments.

AN ASEPTIC ANTITOXIN SYRINGE WHICH MAY BE THOROUGHLY STERILIZED.

By EMIL HOTZEN, M.D.,

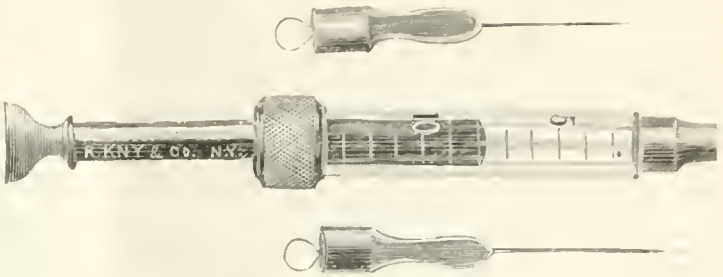
PHYSICIAN TO THE DEPARTMENT FOR DISEASES OF CHILDREN, GERMAN DISPENSARY, NEW YORK CITY.

A HYPODERMATIC or aspirating syringe, which can be rendered absolutely aseptic, without deterioration, is a desideratum which has, so far, not been offered.

I believe that the instrument I have devised, and which is here shown, will fill this want. It consists of a glass barrel, graduated, to the lower end of which is fastened a cap, for the reception of the needle, which is fortified by being attached to an elongated steel knob, which fits snugly into the capping. The other end of the barrel is supplied with a band of metal, which is threaded, so as to receive the screw cap that serves to hold the piston in place. In this screw cap is placed a circular disc of cork, which answers for packing, and contracts or expands as the screw is tightened or loosened, thus controlling the movement of the piston within the barrel. The piston consists of a hollow metal cylinder, fitting snugly within the barrel, and is supplied with a thumb handle.

From this description it will be seen that the complete syringe consists of only five parts—the glass barrel, cylinder piston, needle, screw-cap, and its cork disc, all of which are detachable and may be subjected to the action of boiling water or steam without being damaged. The threaded band and cap of the barrel are not cemented on, but are fitted on the glass while at a high temperature, as a tire is fitted on a wheel. Should the cork disc become softened or otherwise unfit for use, it may be discarded and another substituted, as several are supplied with each case.

Accompanying each syringe is a metal clamp, with a fenestra at each end to hold the needles, two in number. On the under surface of this contrivance is a



third clamp, which holds two or three cork discs, always ready for use.

The syringes are made in two sizes; No. 1, for ordinary hypodermatic use, morphine, etc.; No. 2, a large size, for antitoxin injections, aspirating, etc. Each is fitted snugly in a metal case; the hypodermic may be carried in the vest pocket without any inconvenience.

The instrument is made by Richard Kny & Co., of this city.

59 SEVENTH STREET.

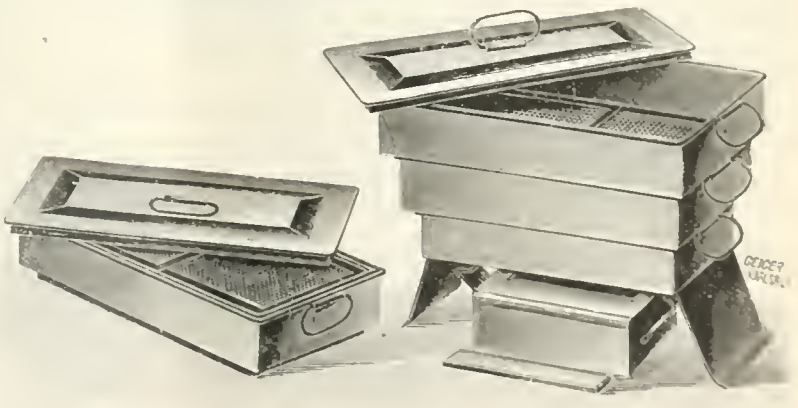
A NEW STERILIZER.

By CARL BECK, M.D.,

NEW YORK.

THE chief disadvantage of all sterilizers of value now in use is their size, which makes it inconvenient to carry them to operations. Most operations require a sterilizer of considerable size. Small apparatus, so-called "pocket sterilizers," allow only sterilization of a few sponges and boiling of the instruments. To remove this difficulty I have devised a folding apparatus, the separate parts of which can easily be put together.

The lower division, which is also the smallest one, consists of a reservoir, which is filled half full with a solution of soda. A wire net, on which the instruments are laid, fits into this reservoir, which fits into the next division of the sterilizer, which again fits into the larger division. If desirable a fourth division can still be set up. The wire sieves can be inserted into the projections of the walls of the division below the reservoir, to receive the dressings, towels, sponges, etc. To



the lower division two folding stands are attached, between which is placed the alcohol lamp when in use. The protection of this lamp is obtained in such a way as to allow of its being carried with safety when it is filled with alcohol. Besides the regular paraphernalia, that is, the alcohol lamp, the wire sieves for the dressings and the wire net for the instruments, two hooks for pulling out the latter and the thermometers, a few instruments, silk, etc., find ample space in the lower division.

So, when division *a* of a medium-sized apparatus is inserted into *C*, and *C* into *c*, and the latter is covered by the lid (*d*) the height of the folded apparatus, amounts to 6 ctm. This is less than one-fourth of the height of the whole apparatus, which, when ready for use, amounts to 27 ctm. After being folded together the sterilizer can either be put into an instrument-bag or can be carried under the arm as it is. Temperature is indicated by the thermometer, which is fitted into an opening in the lid ; two quarts of water after eight minutes can be heated so far as to fill the whole sterilizer with steam of a temperature of 100° C. (212° F.) Anthrax spores, dried on silk ligatures, showed no cultures after they had been exposed to the steam for fifteen minutes.

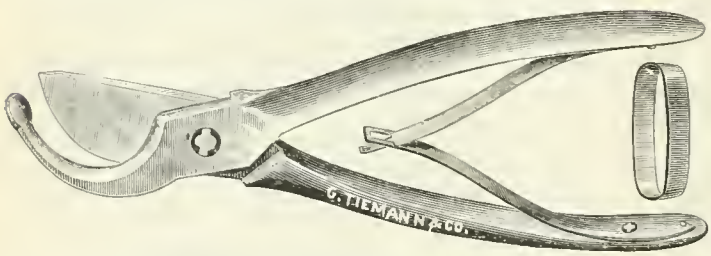
The apparatus is made by Th. Schuaker, of Heidelberg (Germany), and can be obtained from R. King & Co., of New York, in four different sizes.

A NEW RIB SHEARS.

By D. St. JOHN, M.D.,

SURGEON TO THE HACKENSACK HOSPITAL, HACKENSACK, N. J.

The following illustration represents a pair of rib shears in which I have aimed to combine strength, ease of cutting, and safety, in a simple and perfectly aseptic instrument. The cutting edge, comparatively short and of pronounced curve, does not crush the rib as does a straighter blade or a bone forceps, but cuts more like a pruning-knife. The lower blade is curved to more closely apply itself to the rib to be resected, and does not impinge on the adjoining rib. The end is probe-pointed, so that the lung and pleura are not endangered in its introduction. The strength of the blade is in its width, that the thickness may not tear the periosteum from the bone which remains after resection. The curve also allows the blade to dip down (desirable in fleshy subjects) and this admits of the



handle being nearly horizontal, where the operator can exert the most force. The blades are separable and the springs are attached by the same kind of lock.

To Mr. J. A. Pharre, of Tiemann & Co., I am much indebted for suggestions as to spring lock and for so neatly modelling the instrument.

A MODIFIED BIVALVE NASAL SPECULUM AND A MODIFIED BOSWORTH NASAL SPECULUM.

By SAMUEL GOLDSTEIN, M.D.,

ATTENDING PHYSICIAN TO THE NEW YORK THROAT AND NOSE HOSPITAL.

The bivalve speculum in use consists of two blades riveted together, and a screw attached to a horizontal bar on the lower blade, fig. 1. This instrument cannot be taken apart for cleaning. I have modified it with that end in view. This speculum has two small pivots on either side of the upper blade, the lower blade having a perforation on each side to fit the pivot. The screw has a hook-like process that fits over the horizontal bar of the lower blade. To take the speculum apart, slip the lower blade by springing the right side of the pivot toward the distal end of the speculum. The screw bar can then be removed.

I have also modified Bosworth's nasal speculum, fig. 2, so that it can be taken apart for cleaning. This instru-

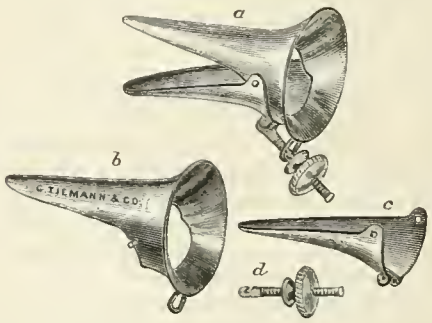


Fig. 1.

ment in its present form consists of two flanges riveted at their distal ends. I have had a reinforced joint

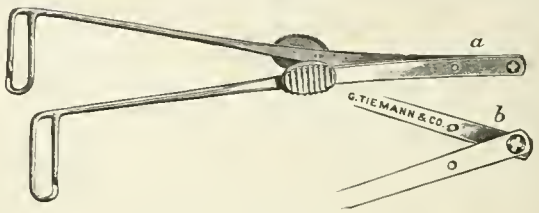

Fig. 2.

made at the distal end of the speculum. The one flange can be lifted, rotated, and thus detached from the other.

These instruments were made for me by Messrs. George Tiemann & Co.

166 East Ninety-third Street.

AN IMPROVEMENT TO JAVAL'S OPHTHALMOMETER.

By FRANCIS VALK, M.D.,

NEW YORK.

In the manufacture of the ophthalmometer of Javal it has been necessary to so fit the barrel of the telescope that it may turn in the upper part of the stand tightly, so that the arc will remain in any position of the circle in which it turns. To accomplish this, the barrel has been carefully ground so that it may exactly fit into the stand, and is then to be turned to the different positions, as that of the first or second, by placing the hand upon the smaller part of the telescope and then turning it to the right or left as may be required.

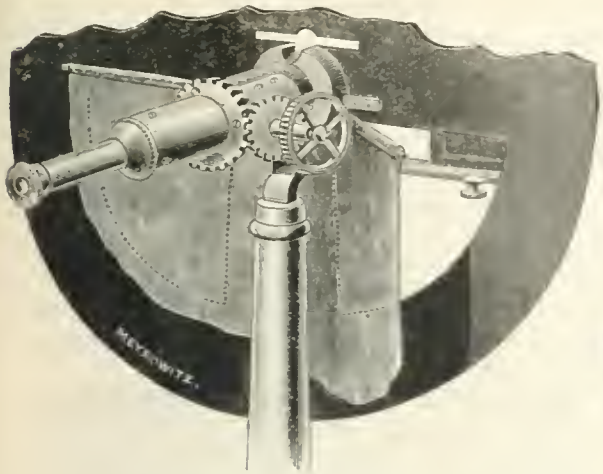
In using my own instrument and those of others I have noticed that the telescope will seldom, if ever, turn smoothly, but will seem to catch or stop, and then by the application of more force we are apt to carry the arc too far beyond the position where the lines on the mires will be continuous, so the arc must be turned back again. This makes it somewhat difficult to always place the arc in the exact position that we wish it, particularly so when the first position may be at some other point than that of ninety. At the same time the constant application of the hand to the polished barrel of the telescope will soon cause it to tarnish.

To obviate these objections I requested Mr. E. B. Meyrowitz to place on the barrel of the telescope a large bevelled gear, fastened securely by four screws, acting upon this, and at right angles to it, we have a smaller bevelled gear, turning on a pinion fastened to a plate, attached to the barrel of the upright part of the stand by four screws. This smaller gear is about one inch in diameter, and is attached to a large milled head about two inches in diameter, so as to be easily turned by the right hand, as the ophthalmometer is used.

By the attachment of this gear motion the barrel of

the telescope is so ground as to turn loosely yet perfectly in the barrel of the stand, and is held firm in any position in which it may be placed by the cogwheels; at the same time it is easily turned by the large milled wheel.

In using the ophthalmometer the position of the arc



can be readily and quickly adjusted to any point or degree on the circle, as we watch the pointers in the refraction on the cornea, and will remain in that position until we desire to turn the arc to the second position.

The above cut will readily show the position of the bevelled gears and the milled wheel for the hand, and their action on the barrel of the telescope.

Since I have had this attachment placed upon the ophthalmometer in use at my clinic at the New York Post-Graduate School, I have been very much pleased with the ease with which the arc is turned, and I consider it a very useful mechanical addition to an extremely useful instrument in the office of the ophthalmologist.

This attachment has been so arranged that it can readily be placed on any of the ophthalmometers now in use, and can be fitted and attached on very short notice, and in a very short time; while the cost is so moderate, considering the increased ease and accuracy with which the ophthalmometer can be used, that I consider it well worthy of examination and trial.

163 East Thirty-seventh Street.

A RECTO-SIGMOID SPECULUM.

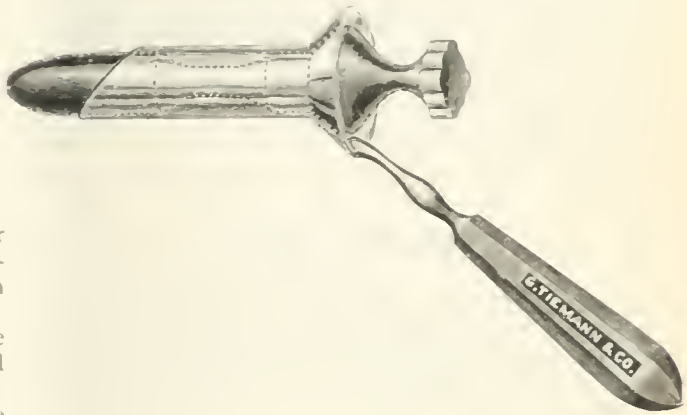
By THEODORE L. ADAMS, M.D.,

PHILADELPHIA.

After several months of constant work with Dr. Martin's improved rectum speculum, described in the Medical Record of September 15, 1894, and finding it equally useful as the designer found it in his practice, and, in fact, being familiar with its excellences as clinically demonstrated by Dr. Martin, I conceived the idea that an enlargement of the field of view would be desirable and might yield better results in practice.

I could see that a cylinder with a diameter equal to the largest diameter of the cone would give the much-desired increase of area at the working end of the speculum; but experience with the Ferguson vaginal speculum of corresponding size proved conclusively that the pain and discomfort caused by its introduction constituted a bar to its use in the average rectum without some device to facilitate its introduction. This difficulty was overcome by temporarily converting the cylindrical into a conical instrument during the time of introduction, by the use of an obturator with a long conical end or beak protruding well out of the cylinder.

The result was remarkable—an instrument easy of introduction and of easy control after introduction. By its use one can bring well into view, without difficulty, all the pathological features of the rectum, or, *per contra*, prove their non-existence. With an instrument of this kind, made of a proper length, it is possible to expose and explore the whole of the rectal mucosa, and to pass well up to the lower curve of the sigmoid flexure, and, by permitting the air to inflate that portion of the colon, as it will in nearly every case if the patient is placed in the proper position, the larger part of the right and superior portion of the lumen of the sigmoid. For this reason I have ventured to call it a recto-sigmoidal speculum. The usefulness and handiness of the instrument are enhanced by the addition of the large, strong handle designed for the original conical instrument. Messrs. George Tiemann & Co., of New York, have made those now in use by me, which give me great satisfaction as means of diagnosis of ob-



scure rectal troubles, and as aids to treatment in cases where we require a larger field of view and more room for manipulation of instruments than we have in the conical form of speculum.

117 South Sixteenth Street.

AN ELASTIC TOURNIQUET.

By JOHN C. SCHAPPS, M.D.,

SURGEON TO DEPARTMENT OF ORTHOPEDIC SURGERY AND JOINT DISEASES, ST. MARY'S HOSPITAL, BROOKLYN, N. Y.

The instrument is a modification of the ordinary rubber tube in that each end is closed by a large ball of the same material vulcanized in. The gap formed by the edges is neatly filled, and the seam smoothly finished. Lodgement for dirt is thus avoided. The tube should be about half an inch in diameter, with a thin wall (about No. 16 gauge). A length of three feet will answer for almost any case, though for hip-joint amputation in a stout subject a longer one will be necessary, and for the limb of a small child a shorter one will be more convenient. The object of the balls, or knobs, is to make the instrument self-fastening. No clamp or tie of any kind is necessary. It may, therefore, be very rapidly applied, and with such little skill as to be particularly useful in emergencies. If it be drawn tightly and the ends simply tied together the balls will prevent their loosening. This, however, is not as rapid as the rolling hitch, or as that shown in the cuts. For

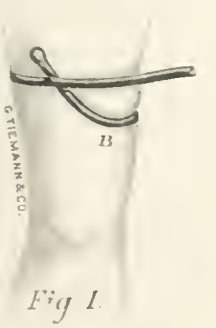


Fig 1.

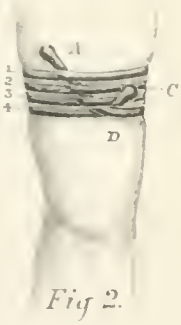

Fig 2.

the sake of clearness of method the tourniquet is represented as loosely put on. In actual use the first turn is stretched around the limb so that the last part of the turn crosses the first part a few inches from the knob (Fig. 1). The limb is thus immediately constricted, and at the same time the ball, with the compressed air in the end of the tube, secures that end so that both hands are free for the application of turns 2, 3, etc. These all cross the first part between the end A and the loop B, which is left uncovered and through which the last knob is thrust from below upward, and thus tightly grasped. In certain situations, as behind the Wyeth pins in hip-joint amputation, where the coils are piled on one another, it is necessary to have the loop B held out of the way. Should it not grasp the end tightly enough a pull on the first part, A, will make it fast. It will be frequently more convenient to leave free ends of several inches. In such cases the air contained in the tube prevents slipping.

This instrument is made by Messrs. George Tiemann & Co., New York.

498 Bedford Avenue, Brooklyn.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 2, 1895.

	Cases.	Deaths.
Tuberculosis	122	94
Typhoid fever	14	2
Scarlet fever	103	10
Cerebro-spinal meningitis	3	6
Measles	61	5
Diphtheria	175	33
Small-pox	2	0

Methods of Isolation Used in the Children's Hospital at Paris.—A correspondent of the *British Medical Journal* gives a description of the Hôpital des Enfants Malades, of Paris. This hospital, he says, claims to have reduced its mortality by a system of isolation of infectious cases. The hospital bears its age upon its face, the paint, plaster work, and worn wooden staircases looking in part picturesquely near the point where old age meets decay. The wards were hot and smelt stuffy. The day was not very cold, but the windows were all shut, and some were streaming slightly. The windows were old and ill-fitting. There was dust about. The wards were very dull and poorly furnished, though the beds seemed good. The wards were divided up by glass partitions into smaller rooms, each containing six or eight children. If the cases in each division were in any way classified with a view to even partial isolation, I did not observe it. The usual antiseptics were on the tables. The children wore nightgowns only, with the exception of one or two little ones, who seemed to be in bed in their petticoats; they may, however, have been partially undressed for the physician's visit. The bedding and night clothes were not so spotless as those at the Hospice des Enfants Assistés. Some of the children were far from well washed; one was dirty. Scaly heads were uncovered, and none of the minute precautions taken at the other hospital were in operation. All the doctors, students, and attendants were in holland blouses; hats were not allowed. Some of the blouses looked as if they had attended operations, and been imperfectly washed. The iron wire "boxes" invented by Professor Grancher were in use round about half the beds. They were iron-wire screens of five or six flaps filled in with woven wire of double or single web, like the wire mattresses on beds. They were painted chocolate color. Their interstices were full of dust, and I should say impossible to keep clean. They were placed so as to surround the beds in various ways, according to situation, sometimes merely hemming the bed in a corner. They were mostly about 4 feet high, and reached about 18 inches to 2 feet above the patient's head when lying down. The following form was observed. The visiting physician alone went inside the screen. The students leaned over, surrounding the bed more closely than they would have done without the screen. They were apparently not allowed to rest their hands on the tops. After examining the patient the physician cast his blouse on the bed, came out, washed his hands, and put on a fresh blouse. The attendants were supposed to do the same after touching the children. At meal times a mackintosh sheet was spread on the bed, and a shallow oblong galvanized wire basket, with a tall handle, was placed on it. The methods employed seemed to the correspondent rather clumsy, requiring an enormous amount of attention.

Some Hints on the Drug Treatment of Phthisis are given by Dr. Frederick C. Coley in *The Practitioner*. He says: I have found salol very successful in the treatment of the diarrhœa associated with phthisis. Remarkably small doses (gr. v. every morning for an adult) are often sufficient, though occasionally gr. x. two or three times daily may succeed where smaller doses have failed. I may remark, in passing, that the same remedy is often useful in the septic diarrhœa of children, but proportionally larger doses are required. Another remedy which has sometimes given good results in tuberculous diarrhœa is morrhuol creosoté. Morrhuol is a material extracted from cod-liver oil. It has been recommended as possessing the medicinal power of the oil from which it has been separated. This seems too good to be true, and it is not in accord with the commonly received theory of the action of oleum morrhuæ. Nevertheless this creosoted compound has certainly yielded very good results in the cases referred to. I am in the habit of prescribing terebene in combination with cod-liver oil in cases of phthisis—ten drops of terebene being mixed with each dose of oil. Terebene is obviously eliminated in the breath. It is to be recommended especially in those cases where the expectoration is profuse or offensive, and where there is a tendency to hemorrhage. Moreover, patients often tell me that the cod-liver oil "agrees better" when combined with it. On the other hand, the terebene itself occasionally disturbs the stomach. I have very rarely found it to cause any irritation of the urinary organs.

For inhalations he prefers:

Tr. iodi ætherealis	℥ ij.
Acidi carbolici	℥ ij.
Creosoti *vel* thymolis	℥ j.
Spiritûs chloroformi	ad ℥ j.

Dr. Burney Yeo's inhaler, made of perforated zinc, is the best, and it also has the merit of cheapness, as it costs less than a shilling. The iodine does not seem to act upon the zinc to any inconvenient extent. About ten drops of the liquid should be used at a time. This often gives much relief in the paroxysms of coughing. About half a teaspoonful of eucalyptol or pure terebene may be sprinkled on a handkerchief, and so allowed to vaporize as near as possible to the nose and mouth of the patient as he lies in bed.

Aphorisms.—The popularity of empiricism is the exact measure of what medicine lacks in order to be an exact science—or of what medical men lack in order to be worthy to represent it.

Should an unscrupulous rival promptly secure for himself a large *clientèle* while your own practice runs the even tenor of its way, do not, on that account, be discouraged; every country contains a sufficient number of intelligent people to maintain as many honest

practitioners as Nature gives birth to; but, as both are in a minority, it naturally takes longer for them to come

"Yes, sir."

"Do you promise not to exchange sponges with the boy next to you and never use any but your own pencil?"

"Yes, sir."

"Will you agree to have your books fumigated with sulphur and sprinkle your clothes with chloride of lime once a week?"

"Yes, sir."

"Johnnie, you have met the first requirements of the modern sanitarians and may now climb over yonder rail, occupy an isolated aluminium seat, and begin making P's and Q's as your first lesson."

Imperative Ideas.—The borderland of insanity is one of the most interesting and important regions with ich our profession has to concern itself. Little e- ntricities, slight oddities, peculiar habitual actions, every now and then manifesting themselves in our tients, and it is not by any means easy to ascribe to ese peculiarities their proper practical or scientific lue and significance. Some will have it that such ings as we have referred to indicate some departure m mental health; while others, admitting the fact, fuse to attach to it any practical importance. It is ways difficult to say when the Rubicon that separates alth from disease is crossed; it is peculiarly difficult the case of the mind, and, if the scientific impor- ce of the determination of this point is greater than so-called practical, the latter is by no means to be glected. By this term are to be understood the ideas words which "arise with painful frequency or vivid- ss; the thoughts which dominate the mind with rbid persistency" (*The Lancet*). Probably every- e has experienced such ideas at one time or another some, no doubt, with much greater vividness than hers. Most of us have probably experienced the dden recollection that perhaps we have not turned e light out or locked the door, actions which have obably become so habitual that the not doing them uld give rise to discomfort. Yet the idea forces it- lf upon us on some particular occasion that the usual utine has been departed from, and so urgent and re- ated is the impression that nothing can dispel it but e fruitless journey downstairs to find that everything as it ought to be. Such experiences, as we have d, are not uncommon; Dr. Tuke instances several them, and he does so with the view of bringing into lief their absolute harmlessness as mental phenomena, hough they may undoubtedly give rise to grave in- nvenience and even danger. Besides imperative eas, strictly so-called, there are also what may be lled imperative emotions or impulses, as Dr. Hack ke points out. Among these is the peculiar impulse ich some people have, when on a height, to throw emselves down. This is probably one of the com- nest impulses that is met with, and it always has emed to us very strange and curious that, in spite of e very great frequency with which it is said to be ex- rienced, it so seldom does really become imperative d lead to the tragedy which it seems to foreshadow. e are, of course, speaking of its occurrence in people parently sane and healthy. No doubt the arches of aterloo Bridge and the top of the Monument could l us tales of the fascination of moving water and of e attractions of an aerial flight, but the unfortunates o have thus perished have too often had experiences ich have culminated in undoubted insanity. One st troublesome instance of imperative impulse Dr. ke mentions, viz., that of a gentleman, the last man the world to use profane language, who had the eatest difficulty in preventing himself from lapsing o profanity in church, and sometimes while walking the street. Such a condition must, of course, be ry distressing, and we are glad to learn that the lan- age which he is impelled to utter does not really be- me articulate, but is represented only by jerking spas- dic movements which may be described as abortive language. Surely this gentleman must be related to another who never could see a bishop without wishing —longingly wishing—to drop into what he called "cursory" language. This was probably an imperative impulse, associated, as they sometimes are, with the idea of Satanic possession. But there are other cases which approach nearer the confines of insanity, and some which cross the dividing line. The patient who is impelled to constantly wash her hands, and who dreads to touch anything for fear of giving rise to the infection or defilement of others, is certainly nearer insanity than sanity, as Dr. Tuke admits; the other, who had the imperative idea that he was pregnant, although at

first he was able to laugh at it as a delusion, actually ended his life in an asylum; so that imperative ideas, harmless as they may be, and no doubt in most cases are, must be regarded as a departure from normal mental health, in however slight a degree, and as such they will have a significance to the practical physician.

The Secret of Long Life.—M. Barthélemy Saint-Hilaire, the famous French scholar and politician, who recently entered on his ninetieth year full of physical and intellectual vigor, has been telling the inevitable interviewer how it is his days have been so long in the land. It is, we are told, the effect of strict adherence to the old precept "early to bed and early to rise," with steady work during waking hours. Every grand old man seems to have a secret of his own. Mr. Gladstone, we believe, attributes his longevity to his habit of taking a daily walk in all weathers, and to his giving thirty-two bites to every morsel of food. Oliver Wendell Holmes pinned his faith on equability of temperature. The late Major Knox Holmes swore by the tricycle, which, in the end, was the cause of his death. Dr. P. H. Van der Weyde, an American octogenarian, not long ago offered himself "as an example of the benign influence of the study and practice of music." Some aged persons give the credit of their long lives to abstinence from tobacco, alcohol, meat, or what not; others to their indulgence in all these things. One old lady, says *The British Medical Journal*, of whom we read not long ago as having reached the age of one hundred and twenty or thereabouts, maintained that single blessedness is the real *elixir vitæ*, and she ascribed the death of a brother at the tender age of ninety to the fact that he had committed matrimony in early life. M. Ferdinand de Lesseps believes in horse riding. Mr. James Payn complains that in his boyhood he "got a little bored with too much horse." The Grand Français seems to think that one can hardly have "too much horse." In a letter recently published, M. de Lesseps delivered himself on the subject as follows: "I shall always feel deeply grateful to Larine, my riding master, who from my earliest years made me share his keen passion for horses, and I am still convinced that daily horse exercise has in a large measure been the means of enabling me to reach my eighty-fourth year in perfect health." Carlyle was also a great rider almost to the end of his long life, and he not only rode, but we believe, groomed, his horse himself. On the whole, it must be concluded that the real secret of longevity is a sound constitution prudently husbanded.

Deaths from Wild Animals and Snakes in India.—The official returns for 1893 show that 21,213 human beings were killed in India by snakes, an increase of 2,188 on 1892; and 5,122 cattle, an increase of 624 on 1892; by wild beasts—meaning thereby tigers, leopards, wolves, bears, hyænas, etc.—2,804 human beings were killed, a decrease of 159 on 1892, and 85,131 cattle, an increase of 7,961 on 1892. The number of wild beasts destroyed was 15,309, a decrease of 679 on 1892; the number of snakes destroyed was 117,120, an increase of 32,331 on 1892.

Decline of the Baltimore Medical Society.—From all reports and appearances there seems to be imminent a decline of the Medical Society in Baltimore. With one or two exceptions, the society proceedings have become draggy, poorly attended, and with little interest shown. There must be some reason for this lack of interest. One reason doubtless is the great increase in the number of medical societies, and especially of the societies of specialists. The ordinary meeting announces three or four subjects, and if these are too specialized, the interest is too contracted and only a small number will attend.—*Maryland Medical Journal.*

The Antitoxin Production.—There is a momentary stoppage in the antitoxin production at Höchst, but a new supply is hoped for in a few days. The concentration of the dose used for immunizing persons near a case of diphtheria has been increased from one-tenth of dose

Forged Diplomas in Italy.—It was recently discovered that the seal of the University of Bologna had been counterfeited and affixed to a number of forged diplomas. It is believed that spurious diplomas, purporting to have been issued from other Italian universities, are also in existence.

Prize Essay on the Abuse of Alcohol.—Some time ago the Austrian Temperance Society offered a prize of 500 crowns for the best essay on how the growing abuse of alcoholic stimulants can be counteracted in schools. Ninety-six essays were received, and the prize was awarded to Professor Ritter von Kraus.

THE CURABILITY OF CANCER WHEN THE LYMPH-NODES ARE INVOLVED.[1]

BY B. FARQUHAR CURTIS, M.D.,

PROFESSOR OF CLINICAL SURGERY IN THE NEW YORK POST-GRADUATE SCHOOL; SURGEON TO ST. LUKE'S HOSPITAL AND TO THE NEW YORK CANCER HOSPITAL.

IN the clinical history of malignant disease there is no factor of greater importance than the secondary involvement of the lymphatic nodes, for upon that point frequently turn our diagnosis and prognosis, as well as our methods of treatment and their results. In fact it is safe to say that, as to diagnosis, we have been in the past far too dependent upon this indication of the malignant character of a suspicious tumor or ulcer, because when glandular infection has occurred it is generally too late to obtain a cure by any operation, be it never so radical. When the disease has begun to spread by the lymphatics, although each gland through which the lymph-stream passes acts for a time as a filter and prevents the infectious material from going farther, this protection is uncertain. Sometimes the node will continue this action until it is greatly enlarged, but more frequently the infectious material will begin to pass through it before any external changes in the gland are perceptible, and thus the disease reaches the next link in the chain, or even spreads itself throughout the entire body, producing the dreaded generalization. When we consider that the glands may be infected even before they are perceptibly enlarged (the usual clinical test for the existence of disease in the glands), and that even at this stage the infection may pass through them and attack the next nodes above, the folly of the time-honored practice of waiting until the glands are involved in order to make the diagnosis of cancer, needs no further demonstration. If we are to hope for a cure we must learn to make the diagnosis before the glands are enlarged, for even the complete removal of all the infected glands discoverable will not give security.

In another point of diagnosis, the distinction between sarcoma and carcinoma, reliance upon the presence or absence of enlarged lymph-nodes, may lead us into error, for later experience has shown that the opinion formerly held that sarcoma does not involve the nearest lymphatic glands secondarily, is not altogether correct, although this infection is not so constant or so early a sequence of that disease as in the malignant epithelial tumors. Thus Dieterich,[2] in 114 cases of melanotic sarcoma which he collected, found the nearest lymphatic glands secondarily involved in twenty-two per cent.; and Poulsen[3] found the axillary glands attacked in fifteen per cent. of 33 cases of sarcoma of the mamma. My impression is strong that secondary disease of the lymph-nodes is even more common in sarcoma occurring elsewhere, although positive figures as to the proportion of cases with and without it are not at hand. I have seen, for instance, the glands in the groin involved with sarcoma of the sole of the foot, those in the axilla with sarcoma of the skin of the shoulder, those in the neck with sarcoma of the tonsil, and all at a comparatively early period. It is chiefly in sarcoma of the bones that infection of the lymphatics is as rare as the older authors were wont to think.

If any rule could be discovered for determining the approximate time when glandular infection is to be expected in malignant disease, it would be of great service, but that period is so variable and the data so uncertain, that we can only predict it in the most general way. In estimating the duration of cancer, we are almost entirely dependent upon the statements of the patients as to the date of its first appearance, and nothing can be more unreliable; for while some persons notice the least variation from the normal, others fail to observe the most obvious tumors or the most marked symptoms; and in many cases the tumor or its symptoms are not definite enough to attract the attention even of the careful, until it has been in existence for a long time. In spite of these difficulties, careful study has shown that the time of secondary infection of the glands in carcinoma depends chiefly upon the variety of the neoplasm and upon the organ which it attacks. Flat-celled epithelioma infects the lymph-nodes very late, ordinary carcinoma earlier, and the soft medullary carcinoma, rich in epithelial cells and poor in connective tissue, invades them very early. In some organs, such as the larynx, the rectum, and especially the skin, the nodes are involved late; while in others, the tongue for example, malignant disease will rapidly attack the glands. While it may be said in general that this second rule is a corollary of the first, and that certain organs are prone to certain neoplasms, and hence the glands connected with any organ are involved early or late according to the form of new-growth which is apt to occur in that part, this is not always the case, for the most common form of tumor in the tongue is flat-celled epithelioma, and yet no organ has a worse record for the early diffusion of the disease beyond its borders than the tongue. Probably the active movements and rich blood-supply of the tongue are largely responsible for this peculiarity. The lip and mamma occupy an intermediate position between the two sets of organs named with respect to the secondary invasion of the glands.

The time of infection of the lymph-nodes has been most thoroughly studied in the breast, in which Gross[1] gives the average date of their involvement as 14.7 months after the tumor in the breast was first noticed. But Poulsen[2] has more recently furnished some data of great importance in this connection. He cites 21 cases of operations in which the mamma was removed for carcinoma but the axilla was left untouched, in which the patients remained well for three years or more. Among these cases there are five examples of freedom of the glands from infection for an unusually long period, two of them being scirrhous tumors which were operated upon two and seven years, respectively, after the first appearance of the growth, and three were ordinary carcinoma operated upon one year (two cases), and three years, after their beginning. In addition to these cases there was an instance of a medullary carcinoma removed as late as six months after it was first observed. These facts prove that glandular involvement may be delayed as late as the dates mentioned

[2] Loc. cit.

for these particular varieties of tumor, otherwise the patients could not have continued in good health. On the other hand, of thirteen patients operated upon in the same manner, who remained free from local return but fell victims to the progress of the disease in the axilla, one woman was operated upon within one month and another within three months after the tumor was first discovered, showing that even at these early dates the glands must have been infected.

These figures illustrate the great irregularity of the time of glandular involvement, and show how impossible it is to lay down any definite laws upon the subject. I have observed among my own cases two instances of late freedom from infection, both, however, in unusual forms of the disease, one being a carcinoma of the nipple with a history of repeated hemorrhage from the nipple for two years before the operation, the other being a typical atrophying scirrhus which had existed for many years (variously given as from seven to fifteen years) before removal, in both of which the glands were enlarged but proved free from malignant changes on microscopic examination. Cases of unusually early infection (in one to three months) are so familiar to all that it is hardly worth while to adduce additional examples ; in fact it is not uncommon to find the glands already involved at the first examination of even a small carcinoma of the breast, in spite of the statement of the patient that she has just discovered the tumor. It may be well to recall to mind that Gross and others have shown that the situation of the tumor in the breast, whether it be in one or another quadrant or in the centre, has no influence upon the date of infection of the lymph-nodes.

The exact method of extension of the disease through the lymphatics is well worthy of study, and we are under great obligation to Heidenhain[1] for his laborious investigations of this point in carcinoma of the mamma, in which he has shown that the infection travels in the first place along the lymph-vessels in the fascia of the pectoralis muscle, and hence in order to obtain a cure it is absolutely necessary to remove this fascia, even in the mild cases in which it does not appear to the naked eye to be diseased. If the growth should penetrate more deeply between the muscular fibres themselves, it tends to diffuse itself parallel with their length and in both directions, so that in such cases it will not suffice to circularly excise the carcinomatous nodule in the muscle, but the entire length of the fibres attacked must be removed from origin to insertion, and in extensive disease the whole muscle must be systematically extirpated. But while these facts are substantially proved, it is well to note in passing that Heidenhain's advice must be accepted with a certain reserve. It is generally admitted that it is necessary to remove the contents of the axilla in every case, and the pectoral fascia as well, even when apparently healthy, for it is never possible to be sure that the disease has not passed beyond the mamma. But in regard to the removal of the entire muscle, there are so many cases on record in which suspicious nodules in the muscle have been simply but thoroughly cut away without removing the entire length of the fibres, and yet no recurrence has taken place, that it is evidently unnecessary to be so extreme in our treatment in every case. The recent advocates for extraordinarily wide and sweeping operations, always removing the pectoralis major with the mamma (Halstead,[2] Meyers,[3]) have not yet had a sufficient number of cases tested by a proper time-limit to prove that their results are any better, as to permanent cure, than those obtained by the ordinary but thorough operation now generally performed, as illustrated by the recent report of Dr. William T. Bull,[4] with twenty-six per cent. of cures. Dr. Willy Meyer's case is only a few months old, and Dr. Halstead has but seven cases followed for three years, with three cures.

It seems to me sufficient, in ordinary cases with slight involvement of the pectoralis muscle, to remove the fibres which are diseased from origin to insertion, with a wide margin, and to reserve the extirpation of the muscle for more extensive disease. The contents of the spaces between the pectoralis major and minor, and underlying the latter, as well as those of the triangle of Mohrenheim, should also be thoroughly removed with the axillary contents ; but it is generally possible to accomplish this without dividing the tendon of the pectoralis minor, or even cutting across the pectoralis major. If it should be found that these spaces cannot be thoroughly cleared without attacking the muscles, the latter should not be spared, and if the pectoralis major be extensively diseased, it should be completely extirpated as suggested by Heidenhain. I have been compelled to remove the pectoralis major eight times (in one patient on both sides) since 1890, and can testify that while this removal somewhat increases the difficulty and danger of the operation, the increase is not great, and the loss of power and motion in the arm is surprisingly small—in fact in some patients it is hardly noticeable.

It is much to be desired that work similar to Heidenhain's should be undertaken in other organs, for it seems probable that the lack of knowledge of the exact course of the disease along the lymphatics leads surgeons on the one hand to neglect important regions where infection is liable to occur, and on the other to make too sweeping operations and to remove tissues which could be safely left undisturbed. The penis would offer a particularly good field for such an examination, for in the early stages of epithelioma of that organ it is probable that the deeper parts are not involved, and that a removal of the tumor, the superficial parts, and the neighboring glands, together with the cellular tissues containing the connecting lymphatics, would enable us to avoid attacking the urethra, and would perhaps save the greater part of the body of the organ, which in the present imperfect state of our knowledge we feel compelled to extirpate down to its attachments to the bone.

It is well established that when the glands are infected the chances for complete eradication of the disease are much diminished, and some authorities appear to think that operations in such cases cannot do more than prolong life. Gross analyzed 136 cases of amputation of the breast for carcinoma, in which recurrence took place, finding that in 43 cases in which the glands were free from infection at the time of operation, the average duration of life from the beginning of the disease was 52.7 months ; but in 93 cases in which the glands were involved the duration was only 39.3 months. In the first set, recurrence appeared in eight months on the average, while in the second it occurred in less than two months. We should note, however, that Gross's collection of cases was made from those published up to about 1885, and gave only 11.83 per cent. of cures, with a mortality of fourteen per cent.—results which have been so much improved of late years that in a collection of cases running up to the end of 1892, I found[1] a mortality of only six per cent., with over twenty-two per cent. of cures, and some individual operators have even better results than these. Poulsen, who may be quoted as more nearly representing modern results than Gross, found that twenty-two per cent. of all his cases (with and without glandular infection) remained well for three years or more, while of 43 cases in which microscopic examination showed that the axillary glands were involved, only four (9.3 per cent.) were well at the end of that time, and in two of these cases the examination had shown that the infection was minimal in extent.

These figures clearly demonstrate how much the danger is increased when operation is delayed until the glands are invaded.

Some personal cases of my own lead me to think that such patients are not incurable, even when some of the glands are thoroughly diseased. The first case, already published,[1] was a slow-growing epithelioma of the floor of the mouth in a patient forty-nine years of age, which I removed by a very thorough operation in January, 1890. In December of the same year he returned with a recurrent tumor involving the lower jaw, and also a single gland in the neck over the carotid, as large as a hen's egg. This gland was dissected out, necessitating the resection of an inch of the internal jugular vein, which was adherent to it but not visibly diseased, and then half of the lower jaw was resected, both bone and gland proving to be carcinomatous on microscopic examination.[2] I have been able to follow this patient, and he still remains well, four years after the second operation. The second case occurred in a laboring man sixty-one years of age, who had an epithelioma on the back of the right hand involving only the skin, but the epitrochlear and axillary glands were decidedly enlarged and hard. I removed the tumor from the hand with free excision of the skin, grafting the wound, and then thoroughly dissected out the glands at the elbow and in the armpit in January, 1891, and the diagnosis of epithelioma of the hand with secondary involvement of the glands in both situations was confirmed by the microscope. I have recently examined this patient, three years after the operation, and can find no trace of malignant disease anywhere. Among my breast cases, one of carcinoma with extensive glandular disease in the axilla still remains perfectly well, three years after the operation. In another case I removed the right breast and axillary contents in 1889, and a recurrent nodule in the scar with the entire pectoral muscle in January, 1890, but in December, 1892, the patient returned with an adherent carcinoma of the left breast, and I was forced to extirpate it with the entire pectoral muscle of that side also; yet, in January of this year (1895), she still remains well, five years after the second operation upon the right side, and two years after that upon the left.

These cases show that even in such advanced disease we need not despair of obtaining a cure by thorough operations, although that fact does not diminish the urgent necessity for operating before the glands are involved, for we have no right to voluntarily incur the risk of delay. The case of epithelioma of the hand is also interesting from another point of view, since it indicates that in some cases the infectious material may pass directly to the nearest glands without contaminating the lymphatic vessels through which it is conveyed, just as muddy water might flow through a pipe without leaving any sediment until it should meet with a filter. I do not believe that this is the rule, but this case shows that a cure can sometimes be obtained by excising superficial epitheliomata and extirpating the nearest lymph-nodes, leaving the intermediate parts. In such a case as that just described, the success of our endeavor to obtain a cure, even if the arm had been amputated, would have depended upon the thoroughness with which the axillary glands were removed, since in them rested, so to speak, the head of the enemy's column, and the infection had already gone beyond the parts which could be removed by a simple amputation. In view of this fact, and of the man's age and inability to support himself if he lost his arm, it appeared legitimate to leave the limb, trusting to the possibility that the lymphatic vessels had escaped infection. Even if disease had appeared later in the course of the lymphatics, an amputation promptly performed would, in all likelihood, have saved his life. This case is not advanced in order to attempt to establish a rule, but merely to illustrate the fact that in some cases the treatment of malignant disease will admit of more conservative measures than those which we are generally forced to adopt. The recent attempts in a similar direction in treating giant-cell sarcoma of the bones by enucleation, leaving the greater portion of the bone, and thus avoiding amputation, have met with fair success and deserve imitation.

In conclusion, I would like to emphasize the fact that extensive operations should not be opposed merely because they are extensive. Any limb or organ should be removed if life can be saved thereby, the only limit to be placed upon the sacrifice being the natural one fixed by the willingness of the patient; and for most men no sacrifice is too great, even when it secures only a few months' delay of the inevitable end. My plea is merely to individualize the cases and to suit the treatment to the form of disease which may be found, and to the particular conditions of the patient. Extensive disease necessitates extensive operations, and in any case the operation must be so planned as to remove every particle of diseased tissue, for only when this is accomplished can a cure be effected. Thorough operation will, as a rule, require the removal of the original tumor, the lymph-nodes of the nearest glandular region, and all the cellular tissue between, if possible in one mass—for instance, the mamma, pectoral fascia, fat on the edge of the pectoral muscles, and axillary glands; the penis, inguinal glands, and intervening subcutaneous fat; and the tongue, and submaxillary glands, with all the intervening cellular tissue in which the vessels run. In such organs as the tongue, when the disease has not crossed the median septum by direct extension, it is often possible to leave one lateral half, owing to the fact that each half has a distinct vascular and lymphatic system. In the breast, however, it is seldom safe to make partial excisions, because the disease spreads so readily, and more particularly because the whole breast is likely to be in a condition which will surely end in the development of the disease. This does not justify, however, the proposition to remove both breasts at once, because, it is claimed, if one is diseased it is probable that the other has also reached a pre-cancerous stage when it may be attacked at any moment. That this claim is unfounded is shown by the rarity of the occurrence of malignant disease in both breasts, either simultaneously or consecutively — according to Gross less than three per cent. of the cases showing bilateral disease. The necessity for radical operations, operations which remove all diseased tissue, cannot be questioned, no matter how extensive they may be, but I believe that it is not necessary to be extravagant in order to be thorough, and that it is possible in certain cases to obtain lasting cures by conservative methods which will spare the patient unnecessary mutilation.

[1] MEDICAL RECORD, 1894, .. 229.

[2] The secondary deposits of epithelioma are frequently carcinomatous.

The Colorado Medical Library Association.—This flourishing organization held its second annual meeting on January 7th. The report of the secretary showed 1,542 volumes of medical works in the library, 200 volumes of bound medical journals, about one thousand volumes of medical journals unbound, and several thousand pamphlets and duplicate medical journals. Thirty-five leading medical journals are subscribed for and 15 others are given. It was announced that transportation had been secured for the gift from the Boston Medical Library to the Association of about 5,000 volumes of medical journals, and that they would soon arrive in Denver.

The Indian Medical Association is a new society recently established in Calcutta. The names of those who have been instrumental in organizing it are among the most representative of the local profession, and it is confidently expected that the society will be an active and influential one.

ON RHEUMATIC AND ALLIED AFFECTIONS OF THE PHARYNX, LARYNX, AND NOSE.[1]

By W. FREUDENTHAL, M.D.,

NEW YORK.

The reports of the rheumatic affections of the larynx, which I will discuss first for the sake of convenience, are still few in number. These affections have been described under various names, so that confusion arose. Thus Fletcher Ingals[2] calls it rheumatic sore throat, while formerly he used the term rheumatic laryngitis. But since he has seen numerous cases, in which other parts of the throat have been affected, "and this at times without involvement of the larynx," he considered the name rheumatic sore throat more appropriate. I for my part should prefer the former cognomen, for although there are undoubted cases of rheumatic sore throat, as we all know, where the larynx is not affected, for which rheumatic angina or rheumatic pharyngitis would be the proper name, yet there are, on the other hand, cases, as we will see below, where the larynx, and only the larynx, is affected. Why not call these rheumatic laryngitis? Max Thorner[3] also, in speaking of a case of rheumatic pharyngitis, and of another of rheumatic laryngitis and pharyngitis, called these rheumatic throat affections. Further, as ordinary cases of so-called chronic rheumatism often approach very nearly the nature of gout or lithæmia, it is well to take also into consideration such affections of the throat as are due to a gouty (Harrison Allen) or lithæmic (Hinkel) diathesis. The last-mentioned author himself admits that lithæmia and gout are closely allied, and says: "The term lithæmia, or the gouty diathesis, may be used interchangeably to describe it in some cases" ("it" meaning the condition of urine, etc.); also that some cases of rheumatic sore throat, described by Ingals, appear to him as instances of a lithic rather than a true rheumatic state. To make things more complicated, Thorner describes a case of "painful throat affection," which was nothing more nor less than the forerunner of a polyarthritis rheumatica. Finally, we find a form described as rheumatic gout or arthritis deformans of the larynx (Archambault, Casselberry, George Meyer-Berlin).[4] Although there is a decided difference between arthritis deformans and true gout of the larynx, my opinion is, that it is impossible in most, if not in all, cases to detect by laryngoscopic examination any distinction between them. But as the medicinal and dietetic treatment for each is so widely different, it is always necessary to determine the primary cause. Only then we will be able to help or even cure our patients.

To begin with the simplest form, the rheumatic laryngitis. Judging from the number of reported cases one would think this disease is extremely rare. But this is not so, as Archambault[4] has already explained. In predisposed individuals the rheumatic laryngitis may be for weeks or months the only symptom of rheumatism, and this very probably is the reason why the correct diagnosis is so seldom made. For in these days of specialism and local treatment *par excellence*, if one sees a case with cough, caused by a dry sensation, with hoarseness and more or less pains in the larynx, accompanied by the general symptoms of laryngitis, one seldom thinks of rheumatism, but satisfied with the diagnosis, laryngitis, applies local treatment, while the real cause of the disease should be treated by internal medication. The following case may be used to illustrate this point.

Mr. S. S——, fifty years of age, saloon keeper, was sent to me five years ago by Dr. Breitenfeld, with cough, hoarseness, and pains in the throat. I find in my case-book the diagnosis, laryngitis. He was treated with astringents, etc., but it took a long time before he recovered. He was suffering from articular and muscular rheumatism at the same time, but I do not remember when the recovery of these affections took place, my case-book giving no date about them. About three years later, *i.e.*, two years ago, he had a similar attack of rheumatism, but more severe, so that he was obliged to remain in bed. His larynx was this time not affected, but later he had a few more attacks of laryngitis, which were usually combined or followed by articular rheumatism in the knees, etc. The latter fact was only made known to me when he came again, on May 2, 1894, with pains in the larynx and trachea, as well as in the knees and calves. Only then did it occur to me that the affection in his larynx and trachea was purely rheumatic. For three weeks he had been treated for throat trouble by somebody else, but without benefit.

The laryngoscopic examination at this visit showed the whole larynx and trachea, as far as one could look down, reddened and somewhat swollen, especially the epiglottis. He was hoarse and complained of severe pain in the right side of his larynx and trachea. The pain increased decidedly with pressure. The pain as well as the inflammation was greatly out of proportion to the local condition observed. This observation is in accordance with those of Dr. Fletcher Ingals. Mr. S—— had a dry sensation in his larynx, which made him cough continually, so that the laryngoscopical examination was quite difficult. In addition he had a bronchitis. I applied the same astringent as before (chlor. zinc), but discontinued this treatment three days later, as he obtained no relief. I then applied external massage by means of my electric vibrator and gave salol internally. I must state that the effect was very striking. For the first time in weeks his cough did not annoy him to any degree, and he was enabled to sleep half the night without awaking. For the next eight days I applied massage daily and his throat felt almost well, when he was forced to go to a hospital, his knees and ankles being so much swollen that he could not walk. At this period the epiglottis and the introitus laryngis were almost normal, the arytenoids still red, and the vocal cords already white on the border line. After two weeks' treatment in the hospital for general rheumatism, during which time he experienced but slight throat trouble, he was discharged cured.

I could further enumerate several such cases, but will not take up your time with repetitions. This one case shows, however, evidently, that in predisposed individuals rheumatic laryngitis may be at times the only symptom or the forerunner of general rheumatism, just as well as the rheumatic pharyngo-amygdalitis, of which we shall speak later on. But it has to be remembered that the first class of cases is very rare.

Under this heading (rheumatic laryngitis) I should like to record the cases of paresis or paralysis of one or both vocal cords, due to rheumatism. In recent literature I find but two cases; one reported by Ehrmann[1] and one by Schmiegelow, mentioned in Dr. Newcomb's article on "The Laryngeal Manifestations of Rheumatism,"[2] while formerly, although quite rare, still they were more frequently published.

The following case came under my treatment April 31, 1894. Miss M. M——, thirty-one years of age, upon whom the radical operation for inguinal hernia had been performed—by the way, without success—left the hospital three weeks ago in a much debilitated condition. Two weeks later she took a drive out of town in an open carriage, and was caught in a heavy rain-storm. She had severe chills and pains all over the body, which she treated with home remedies. One

morning she noticed that she was hoarse, and experiencing pains in the throat, and a sensation as if a foreign body had located in her larynx, she decided to consult a physician. By this time she had become almost aphonic, and I found upon examination the larynx reddened and complete immobility of the left vocal cord. As I discovered neither tubercular glands, aneurism, nor anything else which could by pressure on the vagus or recurrens produce this phenomenon, and as her history pointed to a rheumatic origin, I gave her salicylate of soda together with potassium iodide, and was delighted to see that all the throat symptoms had disappeared by her second visit, which occurred six days later. No local applications had been made, as the patient had told me she could visit me but seldom. In fact I saw her only once afterward, a week later, when all the other symptoms of rheumatism had disappeared also. The iodide of potash had been given only in very small doses. In this case the appearance of a paresis of the vocal cord a few days after exposure to a very severe draught, the presence of rheumatic symptoms in other parts of the body, the absence of any other affection which could explain the paresis, and the prompt disappearance of all symptoms after administering salicylate of soda, confirm the diagnosis of a rheumatic paresis. In all these cases as in our own, improvement follows quickly the antirheumatic treatment, but relapses are not uncommon.

Another class of cases widely different from these exudative inflammations, are those of articular rheumatism of the larynx. This form is easiest to diagnosticate, when other parts of the body are also affected. When, however, no rheumatic history is found and the disease is limited to the larynx alone, it is sometimes of the greatest difficulty to make a correct diagnosis.

Allow me to cite the following case as example.

On June 10, 1893, Annie F——, aged seventeen, and born in Hungary, came to the German Poliklinik. She complained of pains, felt for several weeks, which were permanent on the left side of the larynx. In spite of the most careful examination, which was repeated twice weekly, I could not discover any abnormality in her larynx. During the months of July and August I was not in the city, and when on my return I saw the patient again, she presented quite a different aspect. The pains were still there, even severer than before. On laryngoscopic examination I found the left arytenoid very much enlarged, the crico-arytenoid joint rather anchylotic, and the movement of the left vocal cord much hindered. Her voice, which had been only slightly hoarse before, was now aphonic. As these signs seemed indicative of a tubercular process, I examined the lungs, but except that the right apex anteriorly was slightly dull on percussion, I found nothing abnormal. The examination of the sputum was also negative. Still, as the case was doubtful, I gave her creosote and applied lactic acid after Krause's method, which always relieved her evidently. At the end of November, 1893, she was stricken with a severe attack of rheumatism, which affected almost all the larger joints of the extremities. During this time—a period of about three weeks—the pains in her larynx became very severe on two occasions, but subsided entirely afterward. The breathing was never interfered with. All this I learned when she returned to my clinic, and on further inquiry, found that she had had rheumatism of a mild form the two preceding winters. She was now entirely aphonic and somewhat dyspnoic, a fact of which she was entirely unconscious, and the left arytenoid cartilage was more swollen than before. I put her on salicylate of soda, tincture of iodine externally, and hot applications over the affected part. But although the swelling of the arytenoid went down slowly, she had pains during the whole winter. As the warm weather approached she felt better, and during the whole month of June complained of no pain whatsoever. My last examination, made July 19, 1894, showed the left arytenoid still somewhat enlarged, so that the vocal cords could not entirely close. The voice was still hoarse, but the pains had not recurred.

Such cases are very rare, and a peculiar fact in this one was, that the patient never complained of any dyspnœa, although it was present to a marked degree, and although the left arytenoid was at times so large that a breathing space could hardly be seen. In very acute cases, however, the dyspnœa sometimes becomes so alarming, that tracheotomy is the only relief.

Thus Archambault reports a case of a woman thirty-one years of age, with articular rheumatism and endopericarditis. The fourth day of her stay in the hospital pains in swallowing and dyspnœa appeared. The dyspnœa grew worse so much, that one morning, during a general visit through the ward, the attending physician had to perform a tracheotomy on the spot, there being no time to remove the patient from her bed to an operating-table.

A similar case was reported only lately by George Meyer,[1] Berlin. It is, in short, as follows: A merchant, aged forty-nine years, was ill with acute articular rheumatism. From the sixth day on the larynx was affected, terrible pains in swallowing, etc., and dyspnœa which forced the patient to sit up in bed all night. On the ninth day there were also signs of a thrombosis of the right vena femoralis, but in spite of all the patient gradually became better. Tracheotomy was at one time imminent, but did not become necessary.

In neither of these two cases, however, could a thorough laryngoscopic examination be made. But after seeing my above case just cited, there is no doubt in my mind that in both instances an acute swelling of one or both crico-arytenoid joints occurred.

My patient never during my observation, *i.e.*, over one year, developed any signs of phthisis, so this disease must of necessity be excluded in diagnosing the case.

The other cases of chronic rheumatism of the larynx, to which we will now return, come so near those forms which are due as well to a gouty condition (Harrison Allen), as those originating from lithæmia (F. W. Hinkel), that I am forced to put them in one class together. The term chronic rheumatism, by the way, expresses so little and has so little in common with the well-defined infectious disease which is called acute rheumatism, that it is entirely abandoned by Sacharjin,[2] who proposes instead to use altogether the name polyarthritis chronica.

As I have seen a few cases of lithæmic as well as of true gouty origin, let me cite one case of each species as an example.

Case I.—J. N——, real estate agent, aged thirty-six, complains of much phlegm in his throat. Since eight years he is hoarse almost continually, and he noticed, as often as his stomach was disordered, that he had pains which he located near the thyroid cartilages, especially on the right side. Since eight days he has a very distressing cough. The larynx was deeply congested down to the trachea, but this disappeared after a few days' treatment. Thereafter all I could see was that the redness and swelling extended only to the epiglottis, and for a time to the posterior wall of the larynx. The vocal cords were partly injected.

As the patient had been treated by a good many physicians without permanent relief, and as the local symptoms were not in accordance with the great pain he felt, I concluded that there must be something more behind this. His urine was examined, and uric acid and oxalate of lime were found in excess. A strict diet, together with alkalies and external massage to the larynx, improved his voice and entire condition remarkably and removed the pains within six weeks. He was discharged feeling perfectly well after a treatment of three months.

[1] Zwei Faelle von acutem Gelenkrheumatismus. Berl. klin. Wochenschr., No. 16, 1894.

[2] Deutsch. med. Woch., No. 25, 1894.

That we had here a lithæmic condition of the larynx, just as Hinkel described it, must be clear to everybody.

Case II.—Mrs. A. B——, forty-six years of age, four months ago had an attack of pleurisy. Since then she complains of pains in her chest and in some of the larger joints. But the main reason she came to me, was on account of a very distressing cough. She told me she had formerly several attacks of gout in the left foot, and her family history was gouty for the last two generations. She has home troubles and feels generally depressed. The chest, with the exception of a few râles, showed nothing abnormal. In the larynx I found the signs of a subacute catarrh, the arytenoids both somewhat enlarged, especially near the vocal processes, and a slight swelling of the interarytenoid commissure. Regulation of diet, magnesia, lithia water, etc., improved her condition very much. No local applications were made to the larynx. She visited me for a few weeks and then disappeared. By this time the congestion as well as the swelling of the interarytenoid space were almost gone, but the swelling of the arytenoids remained almost the same. They were surely not diminished in size. She felt improved, however, and coughed very little.

I did not hesitate to make the diagnosis, gout of the larynx, as the patient's history was so distinctly characteristic of gout, and as the treatment improved her general as well as local trouble. Whether the enlargement of the arytenoids was due to a partial ossification or to a gouty deposit, I do not attempt to decide. There is only one thing in favor of the latter supposition, and that is the greater swelling near the vocal processes. But this is a supposition which only occurred to me after reading an old article of Virchow's on rare gouty deposits.[1] At the autopsy of a sixty-five year old man who had died of pneumonia, and who had had swelling and pain in the right ankle, Virchow found accidentally a white kernel the size of a pin's head, which glistened through the mucous membrane. The arytenoids as well as the other cartilages of the larynx, were ossified and transformed almost entirely into spongy tissue. The "tophus" was imbedded exactly in the perichondrium of the vocal process. Surely such a pathological lesion is very rare, and the above-cited case of Virchow's leads me to conclude that my case was similar, although no absolute diagnosis could be reached without an autopsy.

Thus we have seen that the larynx was the seat of an exudative inflammation, or, as it has been called, rheumatic catarrh. We have further seen a true rheumatic localization, which affected not only the mucosa, the muscles, and the nerves, but also the joints. In all of these cases an antirheumatic treatment brought improvement. On account of the similarity of the symptoms, we have also seen cases of gout and lithæmia affecting the larynx, as pointed out by Harrison Allen and Hinkel, and as proven by post-mortem examination by Virchow, and later by Sacharjin, and now we come to the second part of our paper :

The Rheumatic Affections of the Pharynx.—You know that in the last year Sahli, at an autopsy of a patient who had died of polyarthritis, found a coccus morphologically identical with the staphylococcus citreus. Sahli is therefore inclined to take this micro-organism as the virus of polyarthritis, and the opinion that rheumatism is an infectious disease is stronger now than it was before.

In this country E. Fletcher Ingals and Max Thorner were the first advocates of rheumatism affecting the pharynx, etc., and you all remember the discussion that was produced on this question in English medical journals not long ago. Now it is an established fact, that angina is often the forerunner or the initial stage of rheumatism, and we speak of rheumatic angina just the same way as we speak, for example, of a scarlatinous angina. We may with Fiedler consider the rheumatic angina as the first effect of the virus which was inhaled with the air and caught in the tonsils or the neighboring parts. Often, after an interval more or less long—as Dr. E. Roos remarks in a recent publication[1]—the general infection of the system takes place. In this respect we see a similarity with the primary lesion of syphilis. Everyone of you has seen such cases, and my observations in this direction are also very numerous. I shall, therefore, abstain from mentioning any single case. There is, however, another pathological condition which I have repeatedly seen during recent years, and which I am unable to interpret in any other way except that it is due to rheumatism. These lesions are benign ulcerations of the pharynx. These ulcers I have seen only in persons afflicted with chronic rheumatism. Although most writers deny that there are erosions or ulcerations in chronic rheumatism, the similarity between the affection described by Heryng[2] under the above title, and my own observations, is so striking that I cannot but bring them together. First I will recite the cases. 1. Mr. J. M. B——, a manufacturer, aged thirty-four years, of this city, came to me October 7, 1893. He was complaining of an irritation in his throat which made him cough. Besides he had much pain in the left side of his throat, so that he hardly could swallow. He had caught a cold three days previous to his visit to me, and soon afterward felt it in the throat. Since nine years he is subject to rheumatism, and he gets these attacks a few times every year. He had a chronic nasal catarrh, lateral pharyngitis, and acute angina. Besides, he had on the left side of the pharyngeal wall, between the centre and the lateral wall, but nearer to the latter, an ulcer, which was so similar in appearance to that described by Theodor Heryng as benign ulceration of the pharynx, that I was forced to consider this as perfectly identical. The ulcer was about one centimetre long and seven to eight millimetres broad, covered with a grayish-white mass, which could not be wiped away. The neighboring parts were somewhat swollen and reddened. Under the impression that this was due to rheumatism, I gave salol internally, six grammes per day, and in three days the ulcer had disappeared. Exactly six months later, *i.e.*, on April 7th, the patient returned with the same complaints, and this time on the right side of the pharyngeal wall there was an ulcer. With the exception of a slight attack of articular rheumatism affecting his knees and feet, he had been perfectly free, until he again caught a cold the day before. I repeated the salol again, and in four days the ulcer had once more healed without a visible cicatrization.

Very similar was the following case of a lady, aged sixty-four, who, on her way from Montreal to this city, had caught a cold, and on the third day afterward consulted me with exactly the same ulcer on the left side as in the foregoing cases. This healed in a few days, and ten days later she had an outspoken polyarthritis rheumatica of the same severity as she had had for a year two years ago. The third case differed in so far as the ulcer was located on the right posterior pillar. The root of the tongue and the right glosso-epiglottic ligament were very much reddened. Healing in one week.

In the following two cases, men respectively aged thirty-nine and forty-two, the ulcer again was on the pharyngeal wall.

Now if we compare my cases with those observed by Heryng, we see that they differ only in one respect, the seat of the ulcers. He saw them always on the anterior pillar, while I only saw them in its vicinity. But I think this is merely accidental, as I do not see any reason why these ulcers should be located just at the anterior pillars. Nor does Heryng give any ex-

[1] Berl. klin. Wochenschrift, p. 575, 1894.

[2] Theodor Heryng : Ueber benigne Pharynxgeschwucre. Sonder, Abdruck aus der Internat. Klin. Rundschau, Nos. 41 and 42. 1890.

planation for it. In other points the similarity is simply remarkable. We have always an ulcer which was one-sided, solitary, and which remained solitary too. It had a typical form and size, appeared under the picture of a catarrhal angina, and healed without leaving a cicatrix. These were the same conditions as in the cases reported by Heryng.

As to the pathogeny Heryng is doubtful. He could not find the cause in a cold, or excess in alcohol or tobacco, nor in anything else. But I think even such a close observer as Heryng is known to be, is apt to occasionally overlook things. But when his attention is drawn to it, he might find that the slight fever, the difficulty in swallowing, as well as the objective symptoms of redness of some parts or angina, are due to rheumatism concomitant, or after an interval followed by it. This will give him the explanation, also, why my patients who got salol were cured in three to six days, while his, without an antirheumatic treatment, took ten to twelve days before they were better. In this connection I might draw your attention to the article by Dr. B. F. Westbrook,[1] where extensive ulcerations of the pharynx took place due to rheumatism.

A bacteriological examination of the ulcers was not made, as they generally healed so very quickly. There was never associated with them syphilis, tuberculosis, nor what I will add here, diabetes. The ulcers remained always solitary. Whether, as Heryng mentions, they were in any way identical or not with the affection described by B. Fränkel as angina aphthosa, *i.e.*, stomatitis aphthosa, without aphthæ in the mouth, I am unable to answer.

Regarding the seat of these ulcers, I do not think we are as yet justified in speaking of certain parts which are predisposed to them. Heryng, whose so-called benign ulcerations of the pharynx I now accept as of rheumatic origin, found them at the anterior pillars; I saw them in four out of five cases on the pharyngeal wall, while Thorner considers the posterior pillars of the fauces (one case of mine), the root of the tongue, etc., as the places mostly predisposed to rheumatic attacks. The observations on these ulcerations, however, are not as yet numerous, and I hope future investigation will throw more light on this subject. I only intended to tell you what I have observed. The last points to be dealt with to-night are :

The Rheumatic Affections of the Nose.—For a long time I have tried my best, while searching the whole literature at my command, to find something that would throw light upon the following observations; but in vain. With the exception of a few remarks, which touched but superficially upon the subject, I found nothing.

It will most likely surprise you to hear of a new disease; but *a priori*, I do not see any reason why we should speak of rheumatism of the pharynx, of the larynx, and not of rheumatism of the nose. We have in this organ a mucous membrane which responds to the slightest deviation of the normal temperature with an inflammatory reaction, we have cartilages, muscles, and nerves just as well as in other organs. Only the articulations are not as typical here as on other parts of the body, but this is of little importance. Naturally, I will not call every little coryza, which follows a catching of cold, rheumatism of the nose, although a great many of these cases are of rheumatic origin. I shall limit myself only to chronic cases, which to my knowledge have not been described in literature. And of such cases, I must acknowledge, I have only comparatively few, but the symptoms and the course of the disease were such that I hope to convince you to-night of the existence of a distinct disease, *i.e.*, nasal rheumatism.

I saw two varieties of this disease : the one with visible changes in the nose, the other without them.

[1] A case of neurotrophic lesion of the tonsil, velum palati, and uvula, complicating multiple neuritis. The New York Medical Journal, November 17, 1894.

Case I.—Mrs. K——, about fifty-five years of age, came to me February 2, 1891. She complained of a cough, which was especially annoying evenings, and of dryness in the throat. On examination, I found a slight bronchitis, an atrophic condition of the nasal and pharyngeal mucosa, and an injection in the pharynx produced by the cough. I saw her twice, and then did not hear anything from her until she sent for me four weeks later. She told me that a few days before she had been stricken with one of her old attacks of articular rheumatism, the right knee and the larger joints of the upper extremities being affected. She had fever, which did not exceed 101° F. Her nose began to close up on the second day of this illness, and now it was entirely stopped up, so that she could not get any air through it. She had and has still headaches and pain in her nose, all of which together prevent her from sleeping. Externally nothing was seen except a slight redness of the whole nose, no swelling. On examination I did not find any parts of the head sensitive to the touch, but as soon as I touched the nose she felt a pain. She experienced the same when I put my speculum into her nose, and I found that the alæ nasi were the most sensitive. They were not thickened, however, nor was anything else visible that was abnormal and could thus explain the pain in this part. The entrance of the nose was free, but further up the whole nose was clogged by a swelling which I thought to be the thickened mucous membrane. There was also present a grayish-white secretion, which both together filled almost the entire lumen of both nostrils. After removing the purulent discharge I applied cocaine, but found that even a ten per cent. solution of it did not reduce the swelling at all. I gave her different medicines, but she did not feel easier on the second, nor on the third, day. On the fourth day only, after applying repeatedly a ten per cent. solution of cocaine, could she breathe somewhat through the nose, but an hour later everything was closed up again. However, she began to improve after that day, and now menthol oil applied on a a piece of cotton gave her some relief, so that she began to sleep during the night. At this time I could see very well that, after reducing the slight swelling of the mucosa of the septum with cocaine, the lower and middle turbinated bodies were very much swollen. On touching them with a probe they felt hard. There was no sign of an abscess.

The fever lasted until the tenth day and then ceased entirely. From the fourteenth day on there was permanently a free passage for the air. The pains in the nose had been at times so severe that they could only be relieved by large doses of morphia. With the improvement in breathing the pain in the nose grew less, until it gradually disappeared about the twentieth day of my treatment. At the same time her articular rheumatism had entirely left her, and she felt well again, although still somewhat weak. I had given her salicylate of soda and salol, but it never struck me that her rheumatism had anything to do with the affection in the nose, although I could not as yet explain all the symptoms in this case. I saw her a week later in my office, when I found her nose almost in the same condition as on her very first visit : the mucous membrane atrophic, the size of the middle and lower turbinated nearly normal, surely not enlarged, and a perfectly free passage for the air. She left for a milder climate and I heard afterward that she felt well.

A year later, March 14, 1892, I was summoned again to the house of this lady. She had, after a very cold spell, again her rheumatism, and at the same time exactly the same symptoms of the nose as last year. She wanted relief for the latter, as she could easily stand the other pains. This attack took the same course as the one of the previous year. The swelling of the turbinated bodies disappeared about the fourteenth day, and with this almost simultaneously the affections in the joints of the extremities. She had the same pain

in the nose and the same swelling and clogging. The last two winters the lady spent in Italy, and I have not heard anything further about her.

Case II.—Mr. M. B——, forty-one years of age, visited me November 9, 1893. He had had erysipelas of the right side of the face, from which he had recovered three weeks ago. Right afterward he noticed that he could not breathe through the nose. This is the reason why he cannot sleep well. Since eight days he has pain in the left side of the nose, and his old rheumatism set in again at the same time. On examination a small red area on the right cheek, over the zygomatic bone, was to be seen, a remnant of the erysipelas. Internally there was on the same side an outspoken atrophy of the mucous membrane and the turbinated bodies, and a mass of crusts filling the whole nostril. It is evident that in this condition lay the reason for the man's erysipelas. On the other, *i.e.*, left side of the nose, I saw a picture which reminded me very much of the former case. A grayish-white mass filling up the anterior portion, after the removal of which I saw the enlarged turbinated body touching the septum, so that absolutely no air could get through. The mucous membrane was red, like in a subacute catarrh, but with the probe it felt hard over the turbinated and the septum. Cocaine had no influence at all; it required treatment of over three weeks before this man could breathe through the left side of his nose. He was ordered hot baths and salol in large doses. His rheumatism disappeared almost entirely by this time, so that he could attend to his business. His pain in the nose, which was never as severe as in the former case, left him then also. Otherwise the course of this attack was so similar to that of the former case, that I do not need to describe it again. Suffice it to say, that when he left me his left nostril was perfectly free for the passage of air, so that there was absolutely no indication for taking away part of the turbinated bone or the like.

I gave the man orders for keeping his nostrils clean, and did not see him again until five weeks later. He was not over his old attack of rheumatism—his wrists being swollen yet—when, after exposure to extremely cold weather, a fresh attack set in together with the same symptoms in his left nostril, *i.e.*, obstruction and pain. The latter, though, was not very severe this time, and the patient, who gradually got accustomed to the obstruction, visited me irregularly. The weather was quite cold, and, in fact, he was afraid to leave his room. Thus he dragged along, sometimes feeling better and then worse, for two months, when his general articular rheumatism was very much improved and his nostril perfectly free. I have not heard from him since. Only in July I saw him once on the street, when he looked very well and said he felt so, too, in every respect. I wrote him last week, asking him to visit me for an examination, but he did not come. I have all reason, however, to believe that he is perfectly cured.

If we consider these two cases once more, we see that a peculiar affection of the nose, connected with pains, fever, and general weakness, set in right after or together with a fresh attack of articular rheumatism. With the improvement of the latter, or shortly before or afterward, the improvement of this peculiar affection goes hand in hand. As soon as a new attack of rheumatism came again, the nose became affected too. Besides, an antirheumatic treatment was the only one that had any effect on the nose; and now, gentlemen, I ask you what else can it be but a part of that general rheumatic state that had infected the whole system? There is no class of diseases in which it could be placed. Mulhall,[1] in a very interesting paper, describes a disease which he calls rhinitis œdematosa. But as the name already expresses it, there must be a condition, at least, similar to œdema, of which no trace was to be found in my cases. Another disease, which might come in question here, is the phlegmonous rhinitis. But in most cases the clinical appearance of a phlegmon in the nose is so widely different from our rheumatic affection, that it cannot be mistaken for it. There are, however, rare cases of phlegmon which remotely might resemble our cases. For these the following differentiation will be of importance: 1. The seat of the phlegmon is mostly the septum, and only in very rare cases the mucosa of a turbinated. 2. The phlegmon is covered by a mucosa, which is either of a decidedly red color (on the septum), or of a bluish-red where an abscess is forming. 3. The mucosa can reach the highest degree of an œdematous swelling, which goes over in some cases to the skin of the nose, the lower eyelids, and even to the whole face. 4. A phlegmon mostly occurs after a traumatism, which can be accidental or operative.

[1] New York Medical Journal, October 14, 1893.

The symptoms were entirely different in our cases. The septum was not affected at all, there was no swelling of any kind noticeable; no abscess was formed, the color of the mucosa was different, there was no œdema of any part of the mucosa, and there was no traumatism preceding the attack. The only symptom that was present in both diseases was the pain. But, of course, this alone cannot confirm a diagnosis, although I consider it of great importance in confirming the diagnosis of rheumatism. So I am compelled to consider the above cases as of purely rheumatic origin.

The second class of cases of rheumatic nose affections are those where visible anatomical changes can be found only to a small degree, or not at all. These cases seem to be more frequent than the former ones. It is a peculiar coincidence, and which I feel like mentioning here, that the above-cited cases concerned two very wealthy patients, while the following cases were all observed in dispensary practice, among very poor people.

Case I.—Mrs. Rose B——, aged twenty-two, a native of Russia, mother of one child, has had pain in the nose for two years. On examination I found as good as nothing, *i.e.*, a slight redness of the nasal mucosa. I therefore inquired further into her history, and found that she had pains in the limbs, and in the finger-, elbow-, and knee-joints. Sometimes she has a stinging pain in the nose and then the eyes begin to water. This lasts from one to three days. She has had this rheumatism since early childhood, and since four years it is severer, but it is seldom so severe that she cannot attend to her household duties.

After hearing this history I concluded that the pain in her nose must be of rheumatic origin, and gave her salicylate of soda. Three days later she felt free from pain in the nose. Whether she had been treated before in a rational manner for her rheumatism, could not be elicited from the woman. But a week later she had pains again, which again were relieved by the drug. So it went on during the whole winter and even during the summer. She had times when she was free from pains in the nose, and times when she had them again. Nevertheless salicylate of soda always relieved her. Since six weeks, *i.e.*, since beginning of June, however, she is free from all pains in the limbs as well as in the nose, so that I could consider her cured at least for the time being. Whether in the event of her remaining in her damp flat she will again develop symptoms of rheumatism next winter, is hard to say, but I am almost inclined to expect it.

Case II.—A weak old woman, sixty-five years of age, from Poland. She complained of great pain in the nose for about nine months. Three months before a projecting part of the middle turbinated bone had been removed in a dispensary, but the pains, if anything, became worse. On examination I found only slight redness at the right side of her nose covering the whole mucosa, and a post-nasal catarrh. I treated her for months, examined her carefully twice a week, and finally transferred her to the nerve department, as no improvement had been effected. But a few weeks

later she returned to me, complaining just as much as before. She was lying all day long on her bed, as she was unable to go about, so much pain did she have. One day, however, she told me that she was suffering from articular rheumatism. She had been subject to it for years, but it had not troubled her latterly. This brought back to my mind the cases I had treated before. I gave her salol, 6.0 grammes per diem, advised her to make hot applications over the nose frequently, and in a few weeks she was perfectly free from all pains. I have not heard anything of her since.

Case III.—A strong German boy, nineteen years of age, who was employed in a brewery. He was in that business for about a year, and had to run frequently from the ice-house to a very hot room. Since five months he had pain in the nose, for which he visited most of the clinics of this city. All that could be seen on rhinoscopic examination was an hyperæmia of the mucous membrane. Only when he told me that he had pains in other parts of the body, and especially in the back and on the right side, I gave more attention to him. I found that he had a dry pleurisy, for which he had been treated at the internal departments of the different dispensaries. I put him upon large doses of salicylate of soda (8.0 grammes per day); at the same time I advised him to apply wet packs around the chest every night. In three weeks the pain in the nose disappeared, and in seven weeks all the symptoms of the pleurisy. I heard of him a few weeks ago, and can state that he is well for over a year now. I must say, however, that on my advice he gave up his occupation and has exchanged it for a healthier one.

Slight pains in the nose with tearing in the limbs, etc., we see quite frequently in the dispensary, since our attention has been drawn to the fact that there is such a thing as rheumatic rhinitis. It would be too long to enumerate more cases, and especially such with slight affections, as they would only be repetitions of the former ones. But in all of them, where I tried successfully antirheumatic remedies, I think I was justified to make the diagnosis ex-juvantibus aut non-juvantibus. What had not been tried, especially in the second case! One colleague even went so far as to amputate a part of the middle turbinated, although the patient always could breathe well through her nose. I cannot blame him for that, as the woman's troubles were great and he tried to remove everything that seemed to be the cause of it. The pain in the nose of this patient was for a long time the only symptom of rheumatism, and I think, when we see more cases, we will find that in predisposed individuals this is often the case. This will prove a further similarity to laryngitis and pharyngitis rheumatica.

Now it will not appear so strange to speak of rheumatism of the nose, although the nose is not an organ of motion in the sense that the knee or elbow is. But we have to consider that we have here muscles and nerves, and I am sure that in some cases, where I could find nothing abnormal, there was a muscular rheumatism of the nose present; while in others, where I found the mucous membrane painful to the touch, it was very likely that the nerves were affected and that the nerve-filaments of the mucosa, being the most exposed, felt the touch most acutely.

Again, in the first two cases cited there must have been something else. We know that cartilages and bones are affected by rheumatism, and not only the epiphyses of the bones, but all parts of the bones (Sacharjin). So we can explain the terrible pain the first patient had on moving her alæ nasi as a rheumatic affection of the cartilages; while the swelling of the turbinated body was due to an enlargement of the bone itself, caused also by rheumatism. But as long as we have no autopsy of such a case, we only have conjectures as to the pathological anatomy of these swellings. However this may be, I hope you will agree with me, when I call these affections rheumatic after I had noticed that they all were combined with general rheumatism, and that all of them were, to say the least, improved by an antirheumatic treatment.

Gentlemen, the enthusiasm of a new idea is often apt to carry us away, and we often trace things into the circle of this idea which do not belong there. So it happened with me too. Whenever a patient came to me with pain in the nose and I could find no objective symptoms, I made the diagnosis, rhinitis rheumatica. It is possible that I made it too often. The following case, however, is a striking example to show how difficult the diagnosis sometimes is, when cerebral lesions are present too. These cases are important for the rhinologist as well as for the nerve specialist.

Mrs. B. O——, aged forty-three, has pain in her nose for three years. It began with itching, which became so terrible that she felt like tearing her nose off. She cannot blow her nose well. No discharge, nor any other symptom present. Eight years ago she had a miscarriage, but afterward had a child again. She has pains in the limbs, especially in the arms and hands, and feels it always when the weather is changing. At such times her left ankle is swollen.

On examination I found absolutely nothing abnormal in her nose. Her physicians told me that they had given her potassium iodide in large doses, without any effect. It is not more than natural that, under the favorable impression which my former cases had made on me, I thought I ought to make the same diagnosis here, and consequently I gave her an antirheumatic treatment. But instead of an improvement her pains grew worse daily, so that she became desperate. She wanted that something ought to be done to relieve her, and by all means wanted an operation. After a few weeks of fruitless treatment I had to give up the idea of rheumatism, and was really glad when I saw one day pus in the middle meatus. Transillumination gave no indication for an empyema, but I decided to make this small operation, with the slight hope that there might be found little pus in the antrum. Nothing, however, was found. The expected relief did not come: on the contrary the pains grew so badly that she was almost frantic, and I must say it was with much relief on my part when she left me. She went to some surgeons and neurologists afterward. Now I hear that she had been in Berlin for the same troubles a year or two ago. There she consulted different authorities, and Professor Mendel, who is one of these, writes that, as far as he could remember, the woman was suffering from a softening in the white substance due to an apoplectic infarct. But at the time he could not yet make a distinct diagnosis.

Dr. L. C. Gray, of this city, who saw her afterward, kindly gave me the following information about the patient. He writes: ". . . she was simply a case of anæmia so profound that it was of the pernicious type, and because of her home surroundings and the difficulty of getting her to follow my directions in full, she received very little benefit from my treatment."

I do not know where the patient is at present, but I do not doubt that some of you will have a chance yet to see her. So far, this case has been the only one where the mistake in the diagnosis has been made. I did not hesitate, however, to record this case, if for nothing else than for the purpose of showing you how puzzling some of these cases are, and how we might encounter in some of them cerebral lesions of a very obscure origin.

943 Madison Avenue.

The Dangers of the Communion Cup are purely imaginary, says our religious contemporary *The Churchman*, and thinks the discussion is not improbably excited by Roman Catholics to scare Protestants into giving up the use of wine at the communion service.

THE PREPARATION OF CATGUT.[1]

By WILLIAM G. BISSELL, M.D.,

BUFFALO, N. Y.

ACTING BACTERIOLOGIST, DEPARTMENT OF HEALTH, BUFFALO, N. Y.

For a long time surgeons have been impressed with the great unreliability of catgut for ligature purposes. Many different methods have been suggested for use in its preparation, most of them proving to be entirely unsatisfactory. Catgut is derived from the submucous layer of the intestine of the sheep. Owing to its source, it can readily be seen that raw gut must necessarily contain a considerable amount of fatty material, associated with which are a large number of bacteria.

It has been demonstrated by Koch and others that the anthrax spore, the reproductive element of the bacillus, has a greater resisting power than any bacterium yet known, or its reproductive element, and it is safe, therefore, to take this spore as the standard for test in the sterilization of catgut. Sheep are especially prone to anthrax, and the late Dr. Volkman recited a case of anthrax infection occurring at the Halle Clinic, which was undoubtedly due to catgut.

The methods most commonly used for preparing gut for ligature purposes are those employing heat, chemical solutions, or the action of both combined. The application of heat is probably best carried out in the method[2] suggested by Dr. George R. Fowler, of Brooklyn. He found that raw gut boiled in strong alcohol at a temperature of 79° C., was sterilized in an hour or little less. Dr. Fowler,[3] two years later, advocated the boiling of the gut in a closed tube nearly filled with alcohol. These methods, though good ones so far as the germicidal action is concerned, are very uncertain as to the condition of the gut after the boiling process has been completed.

Alcohol itself is very little of a germicide,[4] not affecting the anthrax spore in one hundred and ten days, the heat in Dr. Fowler's methods being the all-important factor. If catgut is heated to a temperature of 85° C. (185° F.) in alcohol, it is destroyed in a very short time.

I am indebted to the J. Ellwood Lee Company, of Conshohocken, Pa., for the following statement: "If catgut is boiled at a temperature a little above the boiling-point of alcohol (78.4° C.) it will make the gut deteriorate in strength." This accords exactly with my own personal experience.

The method of preparing the Fowler tube is as follows: The raw gut is placed in a glass tube nearly filled with alcohol and hermetically sealed, it is then heated to the boiling-point of the alcohol, and allowed to boil one hour. Boiling the alcohol in a closed tube increases the pressure on the liquid, thereby raising its boiling-point, and as this must not be above 85° C., you can see that you run great chances of producing a worthless article. It is far better in the heat-alcohol method to boil the alcohol under ordinary atmospheric pressure, as this gives a constant temperature and not as liable to mishap.

Dr. C. N. Dowd,[5] Surgeon to the New York Cancer Hospital, has suggested the use of an apparatus which carries out this idea perfectly, the apparatus being so constructed that the vapor of the alcohol is recondensed and is used over again.

Dr. Jay O. Nelson,[6] of Chicago, offers a practical suggestion in relation to the Dowd idea of recondensing the alcohol. Dr. Nelson uses an ordinary glass jar, containing sufficient absolute alcohol as to completely immerse the gut. The jar is set upright in a water-bath, and a good-sized piece of ice placed on top. As the vapor rises from the boiling liquid it comes in contact with the cool surface above, is condensed, and falls back into the jar. It is the practice of some to use fractional sterilization in the boiling alcohol process. This is entirely unnecessary, as bacteria development does not occur in ninety-five per cent. alcohol.

Another common method of heat sterilization is by substituting aniline oil in place of the alcohol. This method is possessed of no special advantage and has the disadvantage of being disagreeable to handle, and very liable to mishap, in that the boiling-point of the oil is about 180° C., and it needs constant care to see that the temperature, indicated by a thermometer immersed in the oil, does not go above the heat limitation of the gut. Dry heat is also used in sterilization; this method being advocated by several European hospitals. Such procedure requires a special apparatus for its completion and is not possessed of sufficient additional virtue to warrant the purchase of an expensive sterilizer, when the same end can be accomplished in an inexpensive way. The methods employing chemical agents consist mostly of carbolic acid and corrosive sublimate as the germicide, and are as a rule inferior to the heat alcohol method.

The use of oil of juniper[1] and chromic acid is advocated by some, but not universally endorsed. The one advantage chromic-acid preparations have over others, is that the gut is toughened by the process and rendered less absorbable, this being of value in certain instances, as in operations on the perineum and cervix.

With the object[2] in view of obtaining the most satisfactory method for preparing gut, not being satisfied with the results obtained by boiling it in alcohol, about two years and a half ago I communicated with most of the large hospitals of the country, asking their methods of preparation and the results obtained. Some indorsed the boiling-alcohol method, others stated that the results were doubtful, others used chemical solutions, and a few went so far as to say that catgut was no good for ligature purposes. After experimenting with most of the formulas furnished me (requiring a period of about eight months) I concluded that gut prepared by maceration in ethereal solutions of bichloride of mercury gave the most satisfactory results, in that it rendered the gut sterile, never destroyed its texture or strength, and required no special apparatus for its completion. The probable originator of the ethereal bichloride solution method was Dr. John C. Schapp,[3] of Brooklyn, and since then several men have experimented in that line. Dr. Louis C. Ager,[4] of the Hoagland Laboratory, has made the following bacteriological experiments with pieces of gut prepared by such method. Dr. Ager took a number of pieces of catgut suture, about an inch and a half long and sterilized them in an Arnold sterilizer for half an hour. These pieces were then soaked in an old sporulating culture of the anthrax bacillus for twenty-four hours. One piece was dropped into a tube of sterile beef-tea, and the others were put into an ethereal solution of the bichloride of mercury, about 1 to 1,000. Those in the bichloride solution were removed at intervals of five, ten, twenty, thirty, and sixty minutes, washed in sterilized water and dropped into tubes of sterile beef-tea. After sixty hours in the incubator there was a prolific growth in the control tube, but the others remained sterile. I have performed similar experiments, taking pieces of raw gut and soaking for sixteen hours in a sporulating culture of anthrax. These pieces were then treated by a formula, the details of which will be given later, washed in sterilized water and each piece planted in culture media. In not one instance was there any growth after eighty-four hours in the incu-

bator. The experiments of Dr. Ager would seem to show that five minutes in an ethereal solution of the bichloride of mercury, 1 to 1,000, is sufficient to sterilize catgut, but there is a certain error to be considered. He did not experiment with the oil-laden raw gut, and my experience has been that it takes at least six hours to complete the process of sterilization. Sterilized silk threads impregnated with the anthrax spore, and then dipped in melted tallow, I found to be sterile after six hours' immersion in the bichloride solution. The bichloride method is as follows: place[1] the raw gut, after removing all colored silk, string, etc., in a 1 to 1,000 ethereal solution of bichloride of mercury and allow it to remain there from six to twelve hours, depending on the size of the gut, then wind on sterilized glass spools and place the spool containing the gut in the same solution for six hours longer. Wash in pure ether and then boil in absolute alcohol at atmospheric pressure for ten minutes, the object being to remove all traces of the bichloride. Gut prepared by this method is absolutely sterile.

Some may claim that the bichloride solution weakens its texture; on the contrary, it hardens it, for gut prepared by this formula will remain longer in a wound before being absorbed than the same size prepared by the heat-alcohol method. The ethereal solution overcomes the protection the oil and fat have against the action of the bichloride, and your germicide has a clear field.

Several large hospitals use methods which carry out the principle of the ethereal bichloride solution to the extreme. It is their practice to place the gut in a much stronger solution for a greater length of time than that suggested. This is entirely unnecessary, because the more manipulating and the stronger the chemicals used to complete the process of sterilization just so much more possible chance you run of injuring the strength of your ligature.

In order to ascertain if the fat was mostly removed by this process, I submitted a sample to Dr. Herbert M. Hill, professor of chemistry at the University of Buffalo, and Dr. Hill reported that after treating a prepared sample with ether at its boiling temperature for five hours and a half he was able to obtain a little less than two per cent. of fatty material, the samples of raw gut originally containing about twenty per cent. by weight. Dr. Hill also treated a similar prepared sample by boiling it in absolute alcohol for the same length of time. He was not only unsuccessful in obtaining any fatty material by this procedure, but the gut actually increased in weight and was rendered so brittle that it was worthless.

This method of preparing gut has been satisfactorily employed at Rochester City Hospital, the Whitbeck Private Hospital, in Rochester, N. Y., and by many surgeons in their private work in that city and others. It is now being given a thorough trial by Dr. Herman E. Mynter, surgeon to the Sisters' Hospital, in this city, and the result of Dr. Mynter's experiments will be given at a later date.

The only valid objection made to it, so far as I know, is that it takes at least twelve hours and ten minutes' time for its completion, with perhaps thirty minutes' actual work. I consider this method superior to the others in that it gives uniform results and there is no chance of mishap.

186 Allen Street.

The Suicide Season.—According to the statistics of suicide in London for the twenty years from 1865 to 1884, analyzed by Dr. Ogle, the favorite month for self-destruction is June, with 1,022 per 10,000 suicides, while December has but 697, the lowest figures of the entire year.

THE PREVENTION AND TREATMENT OF OPHTHALMIA NEONATORUM, AND THE NECESSITY FOR MORE EFFICIENT LEGISLATION TO PREVENT BLINDNESS FROM THIS CAUSE.[1]

By CHARLES H. MAY, M.D.,

NEW YORK.

CHIEF OF CLINIC, DEPARTMENT OF DISEASES OF THE EYE, AND INSTRUCTOR IN OPHTHALMOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK; PROFESSOR OF DISEASES OF THE EYE AND EAR, COLLEGE OF PHYSICIANS AND SURGEONS, BOSTON; ETC.

It is the purpose of this paper to prove that, although legislation to prevent the occurrence of blindness from ophthalmia neonatorum was effected in September, 1890, it has not been successful in materially reducing the disastrous effects of this disease; secondly, I wish to suggest a modification of the law which will, if enforced, be more certain to diminish the number of cases, or at least make it exceptional for blindness in one or both eyes to result.

Previous to speaking of necessary legislation, it will be well to review briefly the methods now used to prevent the occurrence of ophthalmia neonatorum, and to treat the disease in the exceptional cases in which proper prophylaxis has been unsuccessful, and in others in which the latter has been omitted.

Almost everyone is familiar with the great success which followed the introduction of Credé's method of prevention. Others had recognized the importance of prophylaxis, and had introduced preliminary disinfection of the vagina of the mother and the use of various applications to the eyes of the new-born (cleaning with water; dry cleansing; solutions of salicylic acid, of borax, of carbolic acid; chlorine water). Credé, however, was the first to advocate the use of an efficient germicide. His method is now carried out in the great majority of lying-in institutions all over the world. Immediately after delivery, the eyes are carefully cleansed with water, and then one drop of a two per cent. solution of nitrate of silver is allowed to fall upon the cornea; this procedure is very often followed by a little redness for a day or two, but no other reaction or inconvenience results.

The brilliant results achieved by Credé in his institute in Leipzig, in which the percentage of cases fell from 10.8 to 0.1 or 0.2 per cent., have been repeated wherever the method was vigorously adhered to. In New York the various lying-in asylums have been practically free from the disease during the past few years; they all employ Credé's method, using one per cent. or two per cent. solutions of silver, and, in addition, disinfecting vaginal irrigations previous to delivery. The following statements from some of these institutions will confirm this practical absence of ophthalmia neonatorum:

In the Sloane Maternity, Dr. E. A. Tucker, the house surgeon, reports that they have had no case of any account among four thousand births during the past six years; two per cent. solution of nitrate of silver and vaginal irrigation before delivery are employed.

Dr. E. J. Sherow, the house surgeon, has written me concerning the Nursery and Child's Hospital, that from July, 1891, to November, 1894, there have been five hundred and sixty-three births, with but one case of ophthalmia neonatorum, and this case was not a serious one; one per cent. solution of nitrate of silver is used.

I was unable to obtain statistical evidence bearing on this subject from the New York Maternity Hospital on Blackwell's Island, an institution averaging over three hundred births a year. Dr. Benjamin Torrens, the present house surgeon, informs me that cases of ophthalmia neonatorum are very uncommon, and cases which result in impairment of sight are rare. Recently,

[1] A paper read at the meeting of the Medical Society of the County of New York, November 26, 1894.

they have been using a saturated solution of boric acid in place of nitrate of silver, and the impression is that the results are just as good; it would be interesting, however, to have this impression verified by statistics.

The following table,[1] given by Fuchs in his admirable essay upon the subject, compares the number of cases of ophthalmia neonatorum occurring before, with those developing after, the introduction of various methods of prophylaxis:

A Comparison of the Frequency of Occurrence of Ophthalmia Neonatorum without Prophylaxis, with the Results of Various Preventive Methods.

Author.	No Prophylaxis.			After Prophylaxis.			
	Births.	Cases of Ophthalmia Neonatorum.	Per cent.	Prophylactic Method.	Births.	Cases of Ophthalmia Neonatorum.	Per cent.
Abegg [2]				Cleansing with water			3.0
Schirmer [3]				Dry cleansing	50	0	0
Bischoff [4]			5.6	Salicylic acid			2.6
Olshausen [5]	550	69	12.5	Carbolic acid, two per cent.; used after ligating the cord	137	12	8.8
Olshausen				Carbolic acid, two per cent.; used before ligating the cord	166	6	3.6
Kruckenberg [6]	1,266	92	7.3	Carbolic acid, two per cent.	82	11	13.4
Koenigstein [7]	1,092	51	4.8	Carbolic acid, one per cent.	1,541	21	1.4
Credé [8]	2,897	314	10.8	Nitrate of silver, two per cent	1,160	1 or 2	0.1 or 0.2
Koenigstein				Nitrate of silver, two per cent	1,250	9	0.7
Kruckenberg				Nitrate of silver, two per cent	730	1	0.14
Felsenreich	1,889	82	4.3	Nitrate of silver, two per cent. First period	3,000	58	1.9
Felsenreich				Nitrate of silver, two per cent. Second period	2,100	21	1.0
Simpson [9]			11.76	Nitrate of silver, two per cent			5.0
Bayer [10]	1,106	136	12.3	Nitrate of silver, two per cent	361	0	0

Personal inquiry has proven that a case of ophthalmia neonatorum is rare in the practice of obstetricians among the better classes. Under such circumstances, very few employ nitrate of silver, almost all depending upon the prophylactic effects of vaginal irrigation, general cleanliness, and cleansing the eyes with solution of boric acid; in the event of the occurrence of ophthalmia, proper treatment readily controls the inflammation, and loss of sight is a rarity. Thus it is evident that cases of ophthalmia neonatorum occurring in New York, are confined to the infants of the poorer classes in whom prophylaxis is omitted by the physician, nurse, or midwife; and even in such cases, blindness would rarely result if proper treatment were applied at a sufficiently early period.

In regard to treatment, there is a practical unanimity of opinion among oculists: 1, Frequent cleansing; 2, cold (or hot) compresses; 3, applications of one per cent. solution of nitrate of silver; 4, treatment of corneal complications.

Every case should be treated as soon as the slightest redness or swelling of the lids is noticed; for we can never be certain, at an early stage, whether such a condition is merely dependent upon a mild catarrhal conjunctivitis, which is seen very frequently in the new-born, or whether we are dealing with the commencement of a true (blenorrhœic) ophthalmia neonatorum.

The eyes should be cleansed very often—the frequency depending upon the amount of discharge; in severe cases, as often as every half-hour; in less severe cases, every hour. The head of the child being grasped between the knees of the physician or nurse, the hands held, and the feet permitted to remain free, the lids are separated gently with the fingers and a stream of lukewarm solution of boric acid is allowed to wash out all accumulated secretion. In separating the lids, we must be careful not to injure the cornea with the nails or with instruments, since the slightest abrasion will serve as a favorable point for the entrance of germs contained in the conjunctival discharge. If the lids are very much swollen, it may be necessary to employ retractors to separate them when we wish to inspect the cornea; but this will not be necessary for irrigation, and will rarely be necessary even for inspection of the cornea, if we remember to place the fingers at the tarsal margin of the infant's lids and not at some distance from the edges. As the discharge sometimes spurts when the lids are separated, the physician or attendant must be careful that none of this material enters his eyes. Various instruments have been devised to facilitate cleansing; one of these consists of a hollow retractor with numerous openings which allow the cleansing solution to wash out the conjunctival sac after insertion; another is a hollow eye-speculum arranged in the same manner; a third consists of an instrument resembling an ear-speculum. But none of these has found any degree of favor, and all are open to the objection of tending to injure the protective corneal epithelium.

A lukewarm, saturated solution of boric acid is employed most frequently as a cleansing fluid; or a solution of salt in the proportion of a teaspoonful to a pint of water may be used. Solutions of corrosive sublimate have been employed, but possess no advantage over boric acid or salt, and there is some question whether they may not act unfavorably upon the epithelium of the cornea. I am in the habit of using the small glass douche, known as the undine, holding from two to four ounces, and find that this method answers admirably for irrigation, and is far superior to the employment of bits of cotton with which to soak up the solution.

Iced cloths should be employed in the following manner: half a dozen small compresses, four-fold and one inch square, are placed directly upon a block of ice; from this they are transferred to the eyes, two at a time, the change being made every minute or two, depending upon how rapidly they become heated. Lint or lintine, which is cotton closely pressed into sheets, answers best for this purpose. The amount of exposure to these cold compresses depends upon the intensity of the inflammation; if the latter be very severe we should continue the applications uninterruptedly day and night; then, as the inflammation subsides, it is well to use the cold less continuously, say every other hour or every third hour, etc.

This is a part of the treatment which requires some judgment and experience, for excessive use of cold favors ulceration of the cornea. I have seen numbers of cases in which the cornea was sacrificed by this mistake. Unfortunately, in these cases we cannot receive information from the sensations of the patient—a valuable guide in cases of blenorrhœa in the adult. In general, it may be stated that as long as the lids continue red, swollen, and tense, cold is indicated, especially if the cornea remains perfectly clear. When the swelling, redness, and tension of the lids subside,

[10] Archiv für Gynäkologie, Bd 30.

we must be careful to reduce the length of exposure to the cold compresses; after these have subsided, if corneal ulceration is present, cold is positively harmful and hot compresses are indicated, just as in any other case of corneal ulceration.

It is not always a simple matter to decide when to reduce or stop cold, and when to apply heat. It is easy enough in cases occurring in robust infants, and when the cornea remains clear; we can then be guided entirely by the appearance of the lids. But given a case of ophthalmia neonatorum occurring in a feeble child (in whom we know that cold in general is not well borne), presenting marked and persistent swelling, redness and tension of the lids, and in whom the cornea shows ulceration, and we are confronted with a condition the treatment of which requires great judgment; it is difficult in such a case to decide whether to continue cold, to stop it, or to change to heat. In every case of this sort we must carefully watch the effect of any change in the temperature of the compresses.

Applications of one per cent. solution of nitrate of silver are useful after the first stage, when the lids begin to assume an appearance approaching the normal, and when the discharge becomes decidedly purulent and creamy. There is no advantage, and there is sometimes harm, in making these applications at an earlier period, and there does not seem to be anything gained by using a solution stronger than one per cent. After the lids have lost their angry appearance, they should be turned out gently and brushed with the silver solution once a day; excess of action is prevented by irrigation with water or solution of boric acid or of salt, immediately after the application, or after half a minute or a minute if we wish more decided action. There is now a tendency, among men who have had much experience with the treatment of this disease, to postpone the use of silver until the third or fourth week, and to use it then merely for the purpose of acting favorably upon the papillary swelling of the conjunctiva existing at this time.

Any extensive consideration of the treatment of complications, such as corneal ulceration and sloughing, staphyloma, prolapse of iris, etc., would not properly come within the scope of this paper. When corneal ulceration exists, it is well to instil one drop of a one-half per cent. solution of atropine once a day; though if the ulceration occur at the periphery and there is a tendency to prolapse of iris, one-third per cent solution of eserine may be indicated. There is a general tendency, even among oculists, not to make direct applications upon ulcers of the cornea occurring in the course of this disease; while this holds good for very extensive ulceration or sloughing, circumscribed ulcers can be advantageously treated by touching them from time to time with tincture of iodine, or even the actual cautery, especially if the inflammation of the lids has subsided. Recently I have seen a number of cases do well under cauterization; and there seems to be no reason at all why such ulcers should not be treated and prevented from spreading, exactly in the same manner as in the case of other infected ulcers. In the course of time, corneæ which seem hopelessly involved, sometimes clear up to an extent which permits some vision.

In treating cases of this disease we must not lose sight of the fact that the favorable response to our interference depends, to a certain extent, upon the general bodily condition of the infant, a fact to prove which Dr. Knapp cites some very forcible illustrations; it is a well-known fact that the most stubborn and disappointing cases are those in which the affection attacks the eyes of feeble and puny subjects.

In considering the subject of legislation for the prevention of blindness from ophthalmia neonatorum, we are justified in assuming that the loss of an eye from this disease means ignorance or negligence on the part of someone. In other words, blindness from this cause is practically preventable; hence the importance of the subject becomes the greater. Statistics from various countries show that about twenty per cent. of all blindness is due to this cause. Magnus[1] found twenty-three per cent. of the blind among young persons, and over ten per cent. among adults a larger proportion than from any other single cause. In the Illinois State Institution for the Education of the Blind, twenty-four per cent. of the cases were due to ophthalmia neonatorum.[2] In the New York State Asylum at Batavia, 19½ per cent. were blind from this disease,[3] and a similar proportion was found in the New York Institution for the Blind. There are at present over fifty thousand blind persons in the United States, and the last census (1890) shows eight hundred and five blind for every million inhabitants. If we consider that twenty per cent. of these fifty thousand were made blind by ophthalmia neonatorum, we can safely count upon a rapid decrease in the number after the introduction of effective legislation. That blindness is on the increase in the United States is shown by the following table:[4]

Table Showing Number of Blind from 1850 to 1890.

United States Census.	Number of blind.	Population.	Number of blind to 1,000,000 population.
1850	9,794	23,191,876	422
1860	12,658	.....	493
1870	20,320	.....	527
1880	48,928	.....	976
1890	50,411	62,622,250	805

It is claimed that the apparent decrease in the proportion of blind from 1880 to 1890 is due to the fact, that in 1880 there were supplementary additions to the returns of the enumerators, such additions having been omitted in 1890.

An examination of the history of legislation for the prevention of blindness from ophthalmia neonatorum, shows that Switzerland was the first country to adopt such laws (1865); Prussia followed in 1878, Austria in 1882, and France in 1888. In this country, New York was the first State to inaugurate laws of this sort (1890). Since then similar legislation has been effected in Maine (1891), Rhode Island (1893), and in several other States. The New York law was passed chiefly through the efforts of Dr. Lucian Howe, of Buffalo, N. Y., and since its provisions have not become generally known, it may be well to add a copy:

An Act for the Prevention of Blindness.—

"1. Should any midwife or nurse having charge of an infant in this State, notice that one or both eyes of such infant are inflamed or reddened at any time within two weeks after its birth, it shall be the duty of such midwife or nurse so having charge of such infant, to report the fact in writing, within six hours, to the health officer or some legally qualified practitioner of medicine of the city, town, or district in which the parents of the infant reside.

"2. Any failure to comply with the provisions of this act shall be punishable by a fine not to exceed one hundred dollars, or imprisonment not to exceed six months, or both.

"3. This act shall take effect on the first of September, eighteen hundred and ninety."

This law would appear to answer every indication; it provides that the management of such cases be taken out of the hands of midwives or nurses, and be entrusted to "legally qualified practitioners." We would expect a material reduction in the number of cases, or at least in the number of cases in which blindness results in one or both eyes. But my investigations have proven that such is not the case; the ophthalmic dispensaries of New York City treat almost as many cases

of ophthalmia neonatorum, in proportion to the total number of eye cases, as they did before the passage of this law. The following tables will prove this:

TABLE SHOWING THE NUMBER OF CASES OF OPHTHALMIA NEONATORUM TREATED AT THE VARIOUS EYE CLINICS OF NEW YORK CITY, FROM 1888 TO 1894.

Year.	Total number of eye cases.	Number of cases of ophthalmia neonatorum.	Cases per 1,000 eye patients.
1888	5,212	36	7.0
1889	5,517	30	5.0
1890	6,052	18	3.0
1891	6,367	43	7.0

1889	657	4	6.0
1890	918	5	5.0
1891	1,027	7	6.0
1892	1,196	4	4.0
1893	1,557	8	5.0
NEW AMSTERDAM EYE AND EAR HOSPITAL.			
2 years. 1889, 1890	1,575	9	6.0
3 years. 1891, 1892, 1893	3,780	19	5.0
3 years. 1888, 1889, 1890	76,366	452	5.92
TOTAL OF FOUR INSTITUTIONS.			
3 years. 1891, 1892, 1893	97,493	488	5.0

A glance at the results given by these tables shows that among 76,366 cases for the three years, 1888, 1889, and 1890, there were 452 cases of ophthalmia neonatorum (5.92 per thousand); while during 1891, 1892, and 1893, among 97,493 cases, there were 488 cases (5.00 per thousand). Thus there has been a reduction of less than one case per thousand since legislation has attempted to diminish blindness from this cause. The actual reduction becomes still less, if we allow for the great increase in the proportion of cases of errors of refraction in dispensary practice, for the past three years, as compared to the previous three years, statistics from these same institutions showing this proportion to have increased from twenty-two per cent. during the first period to thirty per cent. during the second.

I am aware of the fact that there might be diminution in the number of cases of blindness, even though the cases of ophthalmia neonatorum which present themselves at the dispensaries showed but slight reduction in number; but this would imply that the general run of such cases was of a milder type than formerly; clinical experience, however, shows that the proportion of cases in which infants are brought for treatment with the cornea hopelessly involved, is just as great as ever. And in the short period of three years the data furnished by the institutions for the care of the blind would be of no value, since such admissions are not made until some years after.

If in these four institutions 137 cases have been treated during the year 1893, it is safe to assume that at least 500 cases apply for treatment at the various dispensaries in New York City annually; of these, probably one-half result in blindness of one or both eyes, owing to the fact that irremediable damage has been done before proper authorities have been consulted; thus, 250 cases of such blindness are seen in the dispensaries alone. It is, of course, impossible to say how many other cases, which are never brought to dispensaries, are sacrificed to ignorance or negligence. Dr. Howe has estimated that the cost of supporting the blind in New York State amounts, directly and indirectly, to a million and a half dollars per annum. Aside from philanthropic motives, therefore, the passage of a really efficient law would be of immense advantage from an economic standpoint.

There are several reasons why the present New York law has not had the desired effect. To enumerate briefly:

1. The provisions of the law have not become generally known among the profession and among midwives and nurses. No attempt has been made to call attention to it. This being the case, midwives would become aware of its existence only through a large number of convictions, with consequent fines and imprisonment for violation. Not more than twelve cases have been prosecuted and convicted since the law became operative.

2. The term "legally qualified practitioner of medicine" allows the midwife or nurse great latitude in the selection of someone to whom to report.

3. The process of prosecution of an infringement of the law involves so much loss of time to the informant—the general practitioner or oculist—that the lack of enthusiasm shown in this direction is not surprising. The New York Society for the Prevention of Cruelty to Children is not only willing but anxious to prosecute every case of violation, but it can only obtain necessary information from the physician who sees the case after the damage to the eyes is done. Through the courtesy of Mr. Jenkins, the superintendent of this society, I have obtained much information concerning the steps necessary in prosecuting. The physician who meets with a case in which non-compliance with the law has resulted in injury to one or both eyes of a child, reports the case to the society; the latter conducts the prosecution, but the physician remains the main reliance in securing a conviction, and without his attendance at the courts they cannot succeed. This involves a loss of time, first at the Police Court on one or two occasions (twice, if the midwife secures an adjournment—

and this the law allows) ; if she is committed, her trial takes place at some future date in the Court of General Sessions. In the Police Court trials, it can generally be arranged to have the case called at an hour suiting the physician's convenience. In the second trial, he must present himself at 10.30 A.M. and wait until the case is called. If the woman possesses a few dollars with which to engage a lawyer, she can secure an adjournment ; in such a case, the physician is compelled to be on hand some other morning at 10.30 A.M., and wait for his chance to testify. After such a tedious process he may have the satisfaction of having caused the punishment of a woman who has added to the number of blind through her ignorance or carelessness ; but even this feeling of satisfaction is apt to be limited when the midwife is fined but a small amount ; he has lost a great deal of time and considerable practice—practically he has given up two mornings and one or two afternoons, and has suffered many inconveniences. Is it surprising that his philanthropic ardor becomes colder after one such experience? Since September, 1890, there have been but twelve prosecutions ; all of these resulted in convictions. In every case a fine was imposed ; in most cases it was small, in many only $10, in one case $100. In no case was the misdemeanor punished by imprisonment.

For these reasons some modification of the law is absolutely essential. I would suggest the following as answering every indication, and as tending to be effective : Every case of ophthalmia neonatorum should be reported to the local board of health or health officer—whether such a case occurs in private practice or in an asylum, whether under the care of a practitioner of medicine or of a midwife or nurse. In the case of a practitioner, whether in private practice or in an asylum, the board of health or health officer need not interfere. In the case of a midwife or nurse, it should be the duty of this board, or of the health officer of the locality, to send an inspector, upon whom the responsibility of the case will then rest. If he finds that the midwife or nurse has called in a competent physician and that the child is being properly treated, there will be no occasion for further interference ; but if he discovers that this has not been done, it shall be his duty to assume charge of the case and to see that the child is properly treated, either at its home or at some hospital or dispensary. He will then also be able to serve as a witness in the prosecution of such cases, and since he is in the employ of the city or town, he will not be justified in finding fault if part of his time is occupied in the courts. I would suggest that the Medical Society of the County of New York appoint a committee who shall draft a bill on these lines, or modified as they see fit.

This subject is extremely important, both from a philanthropic and an economic standpoint. Every case of blindness prevented means a saving of a large sum to the city or State. Under such circumstances the State or city could well afford the salary of the necessary inspectors. As showing the possibilities of proper legislation for the prevention of blindness from ophthalmia neonatorum, I cannot do better than to close with the remarks of Dr. A. E. Prince, of Springfield, Ill., who in speaking on this subject before the Illinois State Medical Society, at its meeting in May, 1893, said : "Professor Horner became the champion of the legislative efforts, and devoted himself, through his personality and skill, toward increasing the efficiency of the law. During his lifetime he proudly enjoyed the knowledge of the fact that no child, born since 1865, was admitted into the large institution for the blind of Zurich with sight lost from ophthalmia neonatorum."

If this result was possible in Switzerland, we should at least make every effort to duplicate it in New York.

Progress of Medical Science.

Cardiac Liver.—According to the Paris correspondent of the *Medical Press*, Professor Hanot has recently delivered an address on this subject of which the following is a *résumé* : The importance of heart disease in the pathology of the liver is easy to comprehend ; the liver sends all the blood it receives, both from the portal vein and the hepatic artery, almost immediately to the right heart by the vena cava, and consequently the trouble in the circulation of the heart must have a considerable influence on that of the liver. Congestion of the cardiac organ must be followed by congestion in the hepatic veins, producing more or less compression of the cellular elements of the liver. But this congestion is not confined to the veins, it is propagated to the capillaries, and then to the ultimate branches of the portal vein, and finally to the vessels of the spleen, pancreas, and to the gastro-intestinal mucous membrane. It is consequently easy to understand that in heart disease the liver is not only increased in volume, but is seriously affected in the *ensemble* of its important functions. Mr. Hanot, in order to render his lecture more intelligible, traced the history of two cases under treatment in the wards. The first was that of a woman affected with mitral stenosis of rheumatic origin. She entered the hospital complaining of progressive weakness and constant oppression. Beside a souffle at the heart the patient presented evident signs of œdematous congestion at the base of both lungs and a slight œdema of the ankles. The liver was not increased in volume, but a little painful to the touch ; no albumin was found in the urine, but on the other hand distinct traces of urobiline were discovered, showing that the liver was already disturbed in its functions. Rest, milk diet, and a little digitalis cleared away all the bad symptoms, and the woman left the hospital. This was a case of simple congestion.

The second case was of an extreme type. A young woman, after two pregnancies, remarked that her abdomen increased rapidly in volume, and when examined, ascites was diagnosed, and the large amount of liquid was accompanied by œdema of the lower limbs. The abdomen was covered with tortuous veins and very distended. The patient was tapped several times, but finally succumbed from marasmus. At the autopsy the heart was found diseased, while the liver was greatly diminished in volume. The origin of the cirrhosis was evidently cardiac, as the woman never took alcohol. Between these two extremes just cited there exist numerous intermediate morbid conditions in which the difference does not consist only in the degree of hepatic congestion, but in the previous state of the organ. Frequently the liver is the seat of disease, derived from alcoholism, successive pregnancies, infectious maladies, etc., simultaneously with an affection of the heart. All cardiac diseases do not, however, affect the liver in the same manner. Mitral stenosis produces the true cardiac liver, while affections of the aortic and tricuspid orifices produce but little alteration in the hepatic organ. The congestion varies in degree ; sometimes it is but little marked ; the complaints of tension and a sense of weight in the right hypochondrium ; the liver is painful to pressure. In more advanced cases the organ is considerably increased in size, and the patients suffer from nausea, vomiting, constipation, or diarrhœa ; the urine is diminished in quantity and its density increased ; jaundice is frequently observed, but rarely ascites. The treatment is frequently subordinate to the primary cause (the heart), but where the hepatic symptoms predominate milk diet, purgatives, and dry or wet cupping will generally diminish the congestion of the liver and bring it back to its normal volume, causing to cease at the same time the tenderness and the dyspnœa.

MEDICAL RECORD:

New York, February 16, 1895.

THE PHYSIOLOGY AND SURGERY OF THE SPLEEN.

IN ancient days the spleen was considered the source of gladness, the *organon risus*. The relation of the viscera to the emotions was told in this way, says *The Medical Magazine:*

> "Cor sentit, pulmo loquitur, fel continet iras,
> Splen ridere, facit, cogit amore jecur."

In later times the spleen got quite a different reputation, and to be "splenetic" was identical with being of irritable humor.

Modern researches show that the functions of the spleen are not connected with emotional states, and that its duties are of a minor character. Of all large organs the spleen is the least necessary to human existence. The present knowledge of the functions of the spleen includes rather more than this, but we are as yet not fully acquainted with its precise work in the economy.

If studious research and laborious experiment could furnish a key to the mysteries of the spleen, it would certainly be found in a monograph by Vulpius, recently published in the *Beiträge zur Klinische Chirurgie*, Bd. xi., 1894. The article in question is entitled "The Surgery and Physiology of the Spleen." The author has collected all the statistics of splenectomy, and finds that the cases number 117. In 58, or 49.6 per cent., death occurred. Eliminating the cases in which the operation was done unadvisably for leukæmia, he finds the mortality to be 34.1 per cent. The spleen is, therefore, an organ which is susceptible of legitimate surgical attack, except in leukæmia, "chronic congestion," and amyloid degeneration. Turning to the physiological side of the question, Vulpius quotes the results of an enormous number of investigations by physiologists, biologists, and clinicians.

Many of the facts given are most interesting, even though they do not of themselves prove precisely what the spleen is intended for. Thus it is found that the spleen swells in acute anæmia from hemorrhage; and while the spleen is thus congested the blood is found to contain the maximum of red cells and minimum of white.

Several experimenters have found that animals survive extirpation of both the thyroid and spleen. In a few cases the thyroid swells after removal of the spleen; but, says Vulpius, "the rarity of this complication, its timely subsidence, and the result of experiments upon animals would tend to preclude the hypothesis that the thyroid and the spleen have the same function. These rare instances of swelling of the gland may be accounted for upon the ground of congestion or blood-changes."

As there is no splenic development after the total removal of the human spleen, the vicarious hypertrophy of an accessory spleen may be considered. Such organs have been found not only in animals, especially in dogs, but are frequently met with in the human subject. When present, they have been found one or more within the ligamentum gastrolienale. They are of a roundish form, without a hilus, and the size of a bean or hazel-nut, or larger.

Rosenmuller saw among four hundred cadavers in North Germany one accessory spleen the size of a walnut. In Southern Europe he found this anomaly in five out of eighty cases. Giesker confirmed the observation of Dupuytren, that this condition is common in young persons, and especially in fœtuses.

It is, therefore, very probable that these accessory organs can assume the function of the extirpated spleen. Unfortunately, the opportunity has never been afforded of making an autopsy upon a person who had survived the operation of splenectomy.

Vulpius has arrived at the following general conclusions concerning the physiology of the spleen: "1. Histological study of the normal splenic tissue shows the possibility but not the certainty of the entrance of colorless cells in the circulation from the spleen. It is evident that the red cells undergo disintegration in the spleen, but there is no ground for assuming that they are formed in the spleen. 2. Comparison of the blood of the splenic artery and vein shows no positive difference. 3. In acute general anæmia the spleen shows signs of increased activity. 4. Removal of the spleen causes a transient decrease in the number of red, and increase in the number of white, blood-cells. 5. The thyroid gland has no vicarious relation to the spleen. 6. The lymph-nodules and the bone-marrow acquire an increased blood-forming activity after extirpation of the spleen. 7. The regeneration of blood is retarded after hemorrhage in persons without spleens."

"These conclusions," says Dr. J. P. Warlasse, who reviews Vulpius's work in *The Annals of Surgery*, "though contradicting certain accepted teachings, offer little that is new, but are of value in that they are based upon accurate scientific data."

Examination of Sputum for Tuberculosis.—Sputum should be collected only in clean, wide-mouthed, well-stoppered bottles, with a capacity of at least four ounces. Suitable bottles can be obtained at any of the depots for the distribution and collection of diphtheria culture-tubes. Care should be taken that bronchial and not pharyngeal secretion is collected, and the expectoration discharged early in the morning is to be preferred. If the expectoration is scanty, the entire amount discharged in twenty-four hours should be collected.—NEW YORK CITY BOARD OF HEALTH.

THE NAVAL MEDICAL SERVICE.

A curious contrast between the Army and Navy, as regards their respective medical departments, is afforded by the annual reports of the medical chiefs of each service. The Surgeon-General of the Army devoted a large part of his report to deploring the reduction in the number of assistant surgeons recently made by Congress, and said that many candidates who were waiting for examination had been turned away for the reason that there were no vacancies. The Surgeon-General of the Navy, on the other hand, said that there were still eight vacancies in the medical corps, notwithstanding that every reasonable effort had been made to fill them. During the year thirty permits were issued to candidates to appear before the naval examining boards, and of this number only three were found physically and professionally qualified for admission as assistant surgeons. This record, showing a rejection of eighty-five per cent. of candidates examined, Dr. Tryon very truly says, "is not satisfactory, particularly when we contrast the large number of properly qualified applicants for similar positions in the Army and Marine Hospital services, and the promptness with which such vacancies are filled. The examination to which candidates for admission are subjected is in accord with the teaching and requirements of our medical schools, being within the capacity of every young medical man properly equipped for the practice of his profession, and the large percentage of failures, as shown by the record of the examining board, can only be accounted for on the supposition that the naval service, from lack of suitable inducements, does not attract the class of men who would tend to advance the standard of professional excellence, or from whom the highest degree of medical and military efficiency might be expected."

It is easy enough to understand that medical graduates do not care to enter a service where they are ranked and made to mess with boys just from the Naval Academy, but it is not so easy to understand why the conditions that make the service especially undesirable are not changed. For many young men, with no special ties, life in the Navy would naturally have much greater attractions than life in the Army, and if the unnecessary humiliations of the earlier years in the service were done away with, any other disagreeable features which are inseparable from a life on board ship would be willingly borne. The examination for admission to the grade of assistant surgeon in the Navy is no more difficult than is that for the Army medical service, yet fewer men come up for it and a smaller proportion of those who do come up are successful. Possibly, now that the Army is closed for a time to medical graduates, the Navy will profit and be able to fill the vacancies in its medical service; but appointments in this service will never be eagerly sought for until a radical change is made in the subsequent treatment of the successful candidate.

The present Surgeon-General is thoroughly alive to the deficiencies and the needs of the medical service. He has already done much to raise the standard of its efficiency, and perhaps he may yet succeed in making an appointment to it something to be eagerly competed for.

SHOULD WOMAN RIDE HORSEBACK ASTRIDE?

One of the riding-masters of a popular riding-school in this city has proposed to give a course of lectures on equestrianism in all its phases. He further proposes to devote a whole evening to the discussion of the question, Should woman ride horseback astride? The questions which he will deal with, put more categorically, are these:

"Is there any reason why the sense of propriety should hinder a woman from riding on horseback astride?

"Is there any reason why a costume, both elegant and modest in design, and which reveals less of a woman's form than the habit worn for the last years, should not be used by woman when riding?

"Will it add to the comfort, ease, repose, relaxation, and firmness in woman's seat on horseback, and thereby increase endurance and facilitate the learning of horsemanship for woman?

"What is the opinion of competent and learned physicians as to the advisability of riding astride, from a physiological standpoint?"

We are sure that many, if not all, of our readers will say that there is absolutely no physiological reason why woman should not ride astride; but probably none of those who say this will consent to let their wives or daughters ride in this way.

The mighty power of fashion, custom, and habit is infinitely stronger than that of reason, logic, or physiology. There are probably more reasons why man should ride side-saddle than that woman should not sit in the natural bifurcated position; for the disease of the Scythians was produced by this latter posture as assumed by the male.

Perhaps, however, some of our readers can conjure up some real physiological argument in favor of the side-saddle style; and if so, we shall be glad to hear from him. So far as physiology goes, it teaches that man should ride side-saddle and woman astride. This may be the final evolution of the matter.

REPORTERS AND MEDICAL SOCIETIES.

At the opening of the last meeting of the Cincinnati Academy of Medicine, says *The Cincinnati Lancet and Clinic*, one of the members rose to a question of privilege, in which he stated that, inasmuch as the Academy is a constituent part of the Ohio State Medical Society and of the American Medical Association, and, as such, professes allegiance to the Code of Ethics of the latter body, attention was called to the frequent presence of newspaper reporters at the meetings, and to the publication of case reports in the daily papers. Whereupon the presiding officer said the point was well taken, and if newspaper reporters were present they would please retire from the room. Three note-books were folded up and their possessors adjourned.

At the New York Academy of Medicine, and at the meetings of the New York County Medical Society, there are always seats reserved for reporters, who are welcome to give to the public anything that is of interest to it. At the meetings of the American Medical

Association, the proceedings are always reported in the daily papers, and we have observed that frequently pictures of the prominent members are to be seen in the columns. The meetings of the Académie de Médecine of Paris are always public, and so are those of all the learned bodies throughout the world. There is nothing specially mysterious or sacred about the discussions in medical societies, nor is there any good reason why they should be held in secrecy. As a matter of fact, they are usually too technical to have any general interest. But we see no reason why the public should not hear what physicians say in open discussion about matters that concern the general welfare. If medical societies degenerate into occasions for bickering and quarrelling, and the airing of personal grievances, their sessions might well be made secret. But there is no other good reason, and we fear that the infant Cincinnati Academy has done a very silly thing. Are its words more precious than those of the Academy of Paris?

A QUESTION OF ETHICS.

A DELICATE question of ethics has been raised by the editor of the *Columbus Medical Journal*. It seems that the medical director of a large and wealthy life insurance company wrote to Dr. Reed, asking his opinion as to the character, standing, and professional skill of a physician who had applied for the position of medical examiner. Dr. Reed promptly replied, giving the desired information and enclosing a bill, with this comment:

"I herewith enclose my bill for services to your company for this information. While I consider it a courtesy to Dr. S——, which I willingly grant, at the same time I consider it of value to your company to know that he is able to do this work, and that when a physician is asked by your company to stand at the back of another, under these circumstances, and especially where so much is involved as there is in your case, that the company asking the same should pay for such services the same as any other professional services."

The medical director thereupon returned the letter of endorsement and bill, with the statement that there was a misunderstanding, that the endorsement had been requested as an act of courtesy to the applicant for position as medical examiner, and the bill would not be paid.

Dr. Reed contends editorially, that when companies ask for information they ought to pay for it. If, for example, he had been obliged to say that the doctor was not a proper kind of man for the place, the company would have been richer in knowledge, and no act of brotherly courtesy would have been performed.

Looking at the matter from a purely business standpoint, it appears that the doctor must be right and the company wrong. Corporations are obliged to get information regarding applicants. It is a matter of dollars and cents to them; they have always relied upon professional courtesy, and probably will continue to do so. But in cases, at least, in which the information is not "courteous," it seems as if the company had enriched itself without giving any returns.

News of the Week.

The Late Dr. A. L. Loomis.—At a special meeting of the Medical Board of Bellevue Hospital, held January 24, 1895, to take action on the death of Professor Alfred L. Loomis, M.D., LL.D., the following resolutions were entered on the minutes of the Board:

Resolved, That by the death of Dr. Alfred L. Loomis the members of the Medical Board lose a faithful and respected associate, the profession a brilliant and honored member, and the people a wise and vigilant public servant.

Resolved, That the members of the Medical Board do sympathize most deeply with his family in their sad bereavement.

Resolved, That these resolutions be sent to the family and be published in the secular and professional press.

ALEXANDER LAMBERT, M.D.,
Secretary Medical Board.

Dr. William E. Wirt.—In the announcement of the election of officers of the Cleveland Medical Society, Dr. William E. Weir was named as President, instead of Dr. William E. Wirt.

Deutsche Aertze-Zeitung is the title of a new German weekly published at Berlin and edited by Drs. Arthur Hartmann and R. Kossmann.

Obituary Notes.—Dr. Cyrus Falconer died in Hamilton, O., January 28th, in the eighty-fifth year of his age. Dr. Falconer graduated in the Cincinnati Medical College in 1837, since which time he had been continuously a practitioner in Hamilton.—Dr. Jamin Strong, for many years Superintendent of the Cleveland Hospital for the Insane, died at his home, January 30th, aged seventy years.

One of the Curiosities of Surgical Therapeutics is the treatment of tubercular peritonitis by insufflations of air (H. Folet, *Revue de Chirurgie*). After removing serous fluid with an aspirator, the peritoneum is blown up like a bag, three or four litres of air being thrown in. The results are said to be good.

New Discoveries in Brain Physiology.—The London lay press has been heralding what is regarded as a new and remarkable discovery in brain physiology. Strictly speaking, the discovery is anatomical rather than physiological. The discovery now on the *tapis*, says the *Medical Press*, is that of Professor Flechsig, Rector of the University of Leipsic. According to a Berlin correspondent it amounts to this, that within the cortex of the cerebrum four connected plexuses are definable, closely resembling one another, but essentially differing from the other parts of the cerebrum in anatomical structure. These four centres lie in the forepart of the "frontal cerebrum," in the temporal lobe, in the hinder lobe, and in the parietal lobule. They clearly differentiate the human brain from that of the lower animals, and they do not exist in new-born children. Flechsig calls them "intellectual centres," or "centres of association," because they concentrate the activities of the organs of sense into higher units. They are connected by numerous systems of fibres. Flechsig draws

a contrast between them and the "centres of sense," the centres of sight, hearing, smell, touch, etc., which produce lower units. He holds that it is only in the centres of association with which these centres of sense are connected by innumerable nerve-fibres that their contents are converted into thoughts. In assuming so much—for we have yet to learn that it is more than assumption—Flechsig is not content. He goes further, and says that these centres of association elaborate the impressions of the senses, their activity being directly wholly inwards, "they are the bearers of all that we call experience, knowledge, cognizance, principles and higher feelings, and also of language." The new "discovery" is evidently only an elaboration and practical application to psychology of old and well-known facts.

The Claim of a Lady Surgeon.—The concurrence of the House during the past week in the Senate bill for the relief of Surgeon Clapp will doubtless, says *The Sun*, adjust a claim that arose a generation ago. This lady, who is a graduate of the Medical College at Oberlin, was employed, it appears, although of course not commissioned, as a surgeon of a volunteer cavalry regiment from November 15, to December 27, 1861, and as an assistant surgeon of cavalry from the latter date to August 25, 1862. These services were rendered prior to her marriage, under her maiden name of Sarah A. Chadwick, which may perhaps be recalled by survivors of the Seventh Illinois Cavalry. The regiment was at that time stationed at Cairo, or else on the other side of the Mississippi River; and Mr. Henderson, of Illinois, in recommending the claim of Dr. Sarah A. Clapp, said that "she rendered valuable service, so valuable that the regiment wanted her as its surgeon, but those in authority were unwilling to appoint a woman." The case is certainly very interesting, and furnishes a well-attested addition to the records of military services performed by the gentler sex during the civil war. It is also a little remarkable that Mrs. Clapp did not present her claim until the lapse of a quarter of a century. However, the House disposed of the matter in a very few minutes after it was presented. The bill carries, we believe, $700 or $800.

The West End Medical Society.—At a meeting of this Society, held February 2d, the following officers were elected: *President*, Dr. F. M. Crandall; *Vice-President*, Dr. Le Roy Brown; *Treasurer*, Dr. H. G. Myers; *Recording Secretary*, Dr. F. J. Brockway; *Corresponding Secretary*, Dr. E. Harris; *Pathologist*, Dr. J. S. Ely.

The Serum Therapeutics of Pneumonia.—At the time when the attention of the medical world is directed to the serum therapeutics of diphtheria and tetanus, a short review of the same method of treatment as applied to pneumonia, given in *L'Union Médicale* of December 8, 1894, may prove of interest. Numerous experiments have been made on animals, and several attempts have been made to treat patients in the same manner. Drs. F. and G. Klemperer have treated twelve cases of pneumonia with the serum of rabbits rendered artificially immune. Each dose consisted of from five to ten c.c. injected under the skin of the buttock. Eliminating five of the cases in which crisis resulted as in the ordinary course of the disease, in the remaining seven each time the serum was administered there was a diminution in the height of the temperature and in the frequency of the pulse and respiration, and the patients made a good recovery. They have also injected eight patients with cultures of the pneumococcus which had been heated to 60° C., and so deprived of toxicity. The results were very satisfactory, the temperature falling soon after the injections. They also inoculated patients with the serum of other patients suffering from pneumonia, obtained immediately after the crisis. After the inoculations the temperature became lower, and frequently defervescence at once followed. Foa and Carbone reported a case of pneumonia which was arrested on the fourth day after injections of the serum of a vaccinated rabbit. Foa and Scolia injected ten patients suffering from pneumonia with from five to seven c.c. of the serum of rabbits which had been rendered immune, the injections being given under the skin of the back. In some of the cases as many as three injections were given; in these (four in number) the crisis appeared to be hastened. Jansen also records cases in which this treatment was adopted with success. Lava has treated ten cases of pneumonia with injections of the blood-serum products obtained from the viscera of animals suffering from pneumonia. The injections produced no immediate or ulterior local reaction. There was also no immediate influence on the temperature, but the thermometric curve gradually became lower; the frequency of the pulse and respiration was diminished. Convalescence was rapid and no complications followed. Taken as a whole, the above series of experiments are satisfactory, and the serum therapeutics of pneumonia deserve further trial and investigation.—*Lancet.*

The Society of Alumni of Bellevue Hospital, New York, gave its fourth reunion dinner on Tuesday evening, February 12th, at the Hotel Brunswick. Dr. Charles C. Barrows, president of the association, acted as toastmaster. The following were the toasts and their respective respondents: "The Medical Board," by Professor William H. Thomson; "The Alumni," by Robert T. Morris; "Our Sister Societies," by Dr. William K. Simpson; "The Clergy," response by Rev. Roderick Terry, D.D.; "The Patient," by the Hon. J. H. V. Arnold, and "Woman," by Mr. Louis E. Bomeisler.

New Medical Law in West Virginia.—The State of West Virginia is apparently to have a new Medical Practice Act, the House bill for that purpose having been favorably reported by the Judiciary Committee of that body. The bill provides that the State Board of Health shall, at such times as a majority shall deem proper, hold examinations for the licensing of practitioners of medicine. The bill provides for both written and oral examinations, "covering all the essential branches of the sciences of medicine and surgery, and the examination shall be a thorough and decisive test of the knowledge and ability of the applicants." Should any applicant profess a desire to practise according to the "homœopathic" school, then the Board "shall call to their assistance a homœopathic physician duly licensed to practise medicine in this State."

Reviews and Notices.

Twentieth Century Practice. An International Encyclopædia of Modern Medical Science, by Leading Authorities of Europe and America. Edited by Thomas L. Stedman, M.D. In twenty volumes, Vol. I., "Diseases of the Uropoietic System." New York: William Wood & Company. 1895.

This rather taking title is the designation under which is to be published what promises to be the most important medical work of this final quarter of the nineteenth century. From the announcement which we have received with the first volume of the series, we learn that the work will consist of twenty volumes, published at the rate of four each year, so that by the time of the appearance of the last volume the somewhat anticipatory title of the series will be justified. The list of contributors is a remarkably strong one, containing the names of many of the best-known authorities in every country of Europe and in America.

In the first volume, treating of diseases of the urinary system, there are five contributors, three Americans and two Englishmen. The first article, which is on Diseases of the Kidneys, is written by Dr. Francis Delafield, of this city. In it the author sets forth, in greater detail than in any other previous publication, his excellent classification of diseases of the kidneys. By the system which he has adopted it is surprising how the difficult subject of renal affections is simplified, and also how time is saved in their description. The present article is but a little over one hundred pages in length, yet the reader rises from its perusal with a clearer notion of the morbid changes in the kidney, commonly grouped under the term Bright's Disease, than he could get from many a treatise three and four times its length. The illustrations, of which there are twenty-six, are beautiful reproductions of micro-photographs of sections of the kidneys, showing the tubes and glomeruli in various stages of inflammation and atrophy. The second article, by Mr. Reginald Harrison, of London, is on the Diseases of the Ureters and the Surgical Affections of the Kidneys. The section on the ureters especially contains a record of much original work in this comparatively fresh field. The next article by the same author is on the Diseases of the Bladder. This treatise is necessarily surgical in character, yet, except in the section dealing with stone in the bladder, there seems to be little that would not interest the general practitioner as much as the surgeon. Two well-written and practical articles from the pen of Dr. G. F. Lydston, of Chicago, follow, taking up the consideration of Affections of the Prostate and of the Male Urethra. In the second article the author's views as to the nature of Urethritis are specially interesting. While recognizing the presence of the gonococcus, he does not seem to regard it as an indispensable factor in the causation of gonorrhœa, or at least of a urethritis indistinguishable in any essential particulars (symptoms, response to treatment, complications, or sequelæ) from the alleged specific form of the disease. Mr. E. Hurry Fenwick, of London, is the author of the next treatise, entitled Diseases of the Urine. This deals with certain morbid changes in the urine, and the diseases with which these changes are associated. Thus the symptom hæmaturia is considered in its relation to the inflammatory, tubercular, cancerous, and calculous diseases of the various portions of the urinary tract. The divisions of this article are hæmaturia, pyuria, accidental albuminuria, cystinuria, phosphaturia, oxaluria, polyuria, and chyluria.

The volume closes with a striking article on the Diseases of the Female Bladder and Urethra, by Dr. Howard A. Kelly, of Baltimore. The first thirty pages of this paper are taken up with a description of the author's method of cystoscopy in the female. The procedure is so rational in its conception, so practical in its results, and withal so easy of execution, that it seems strange it should not have been conceived of before. The method is described very clearly, and illustrated with numerous drawings and process reproductions of photographs. Finally, a very complete index renders all this mass of original work readily available.

The preceding description, brief as it necessarily is, will serve to give an idea of the individual articles, and we need say but a word concerning the volume as a whole. Owing to the systematic arrangement followed by the editor, we have here a procession, as it were, of the affections of the entire urinary tract, beginning with the kidneys and ending with the urethra. The only remaining disease, which might be classed among those of the urinary system, is diabetes mellitus, which we see from the recently issued prospectus is to lead off the second volume, apparently as a connecting link between diseases of the uropoietic system and those sometimes called nutritive, such as obesity, gout, and rheumatism. The illustrations of the volume are, as we have mentioned in speaking of the separate articles, beautifully executed and most instructive, and together with the clear type, excellent printing, and substantial binding, make a volume of which the publishers may well be proud. We shall await with interest the appearance of the succeeding volumes of this great work, which, if we may judge from the unequalled list of those who are to contribute the separate articles, is destined to be the authoritative treatise on the practice of medicine for many years to come.

Diseases of the Chest, Throat, and Nasal Cavities. Including Physical Diagnosis, and Diseases of the Lungs, Heart, and Aorta. Laryngology and Diseases of the Pharynx, Larynx, Nose, and Thyroid Gland and Œsophagus. By E. Fletcher Ingals, A.M., M.D. Third Edition. Revised. Two hundred and forty illustrations. New York: William Wood & Company. 1894.

This most elaborate work is divided into thirty-seven chapters. Commencing with a detailed description of the most approved methods of physical diagnosis, the reader gradually finds himself advancing into percussion, auscultation, and physical diagnosis generally. Nothing has been omitted, while detailed descriptions, *e.g.*, of the plessigraph, make it appear how careful the author has been to describe accurately all the new and accessory aids to diagnosis.

In the chapter on tuberculosis the modern physician will readily recognize that most valuable aid to diagnosis, *i.e.*, tubercle bacilli. The illustration is very exact and perfect. In the chapters on cardiac diseases the sphygmograph receives proper consideration.

A very practical article is found on page 249, entitled "Tachycardia." On page 250 the article on "Bradycardia" is also very instructive.

Commencing with Chapter XVI., on the throat, we learn of methods of examination until we reach Chapter XVIII.; here the description of acute sore throat is quite novel. We do not remember seeing this diagnosis, plausible as it is, in any other work. Most interesting chapters on larynx and nasal disorders, and all details, medicinal and operative, are carefully discussed.

The illustrations are excellent; type clear; and the work deserves careful reading; for the physician looking for recipes this book will supply a great many. The author is to be complimented on the thorough and concise manner in which he handles every article.

A Manual of the Practice of Medicine. Prepared especially for students. By A. A. Stevens, A.M., M.D. Third Edition. Revised. Illustrated. Philadelphia: Saunders, 925 Walnut Street. 1894.

This book, of about five hundred pages, is one of the most practical written. It is full of points on all modern methods of examination, giving microscopical and

chemical methods to date, besides numerous prescriptions which are always eagerly sought for by the young physician. The type is clear, and it well deserves the name of manual.

Travaux D'électrothérapie Gynécologique. Archives semestrielles d'electrothérapie gynécologique, fondées et publiées par le Dr. G. Apostoli. Vol. I., Fascicules I. and II. Paris: Société d'Éditions Scientifique. 1894.

This is an interesting collection of papers by the followers of Apostoli in different countries, bearing witness to the value of his method of treating various pelvic affections by electricity. With many of these the reader is already familiar, as they have appeared in the medical journals. America is well represented. The book will be read with much interest by those who desire to know what has been accomplished in gynecological electro-therapeutics during the past decade.

A Clinical Manual of Diseases of the Eye, Including a Sketch of its Anatomy. By Dr. B. St. John Roosa, M.D., LL.D. Illustrated by one hundred and seventy-eight Engravings and two Chromo-lithographic Plates. Large octavo, pp. 617. New York: William Wood & Company. 1894.

This new manual of diseases of the eye is divided into four parts, classified as follows: Part I., "A Sketch of the Anatomy and Physiology of the Various Parts of the Eye and its Appendages," 114 pages; Part II., "The Relative Frequency of Different Diseases of the Eye, Methods of Examination, Therapeutics, and Surgery of the Eye," 110 pages; Part III., "Diseases of the Eyelids, the Lachrymal Apparatus, the Conjunctiva, Eyeball, and Orbit," 204 pages; Part IV., "Conditions of the Eye Requiring the Use of Glasses, Errors of Refraction and Accommodation, Strabismus, Affections of the Ocular Muscles," 143 pages. An ample glossary and index complete the work.

The author, in presenting this work, invites an impartial hearing to his views on hyperopia and asthenopia, found in detail in the fourth part of the work; and the history of the developments of this later addition to the literature of ophthalmology is an elaboration of the author's sound views, founded on Donder's theory of asthenopia published about fifty years ago.

In view of the prolific output of text-books on diseases of the eye in the English language, within the last decade, the author vindicates his efforts to present the results of a long professional experience by a desire to satisfy a debt which, as teacher and clinician, he owes the medical profession. A critical perusal of the terse and practical embodiment of the author's experience justifies him in the position taken. The fourth part must be regarded as the *pièce de résistance* of the book. It is as true of ophthalmology as of geology, that, in certain departments, it is well-nigh impossible to write anything new or original.

Under the topic of the ophthalmoscopic appearances of the retina, it is refreshing to read the confirmation of Loring's theory of the light streak on the arteries and veins of the retina. Loring's theory was that it was due to refraction of rays of light passing through the blood-column of the vessel, striking the underlying tissue, and reflected back through the vessel and blood-column into the eye of the observer. The theory was not concurred in by Donders, Jaeger, Schneller, and others, because Loring used a carmine solution instead of a column of warm blood. Later experiments have verified Loring's position, and it may be regarded as established that, the white light streak accompanying the healthy retinal vessels is due, not to a reflection of light from the height of the vessel, but rather to a refraction of light-rays passing in and out of the vessels themselves.

Under the topic of anatomy of the optic nerves, there is an admirable and concise description of the whole course of the optic tracts, accompanied by Fuchs's schematic diagram, so that any student may familiarize himself with the clinical conditions of hemianopsia, both homonymous and temporal or nasal.

Scarcely eight pages are devoted to the study of the general physiology of vision—an ideal and romantic chapter to the student of physiological optics. The innervation of the iris-sphincter, the play of the equatorial and meridional fibres of Bowmann's muscle of accommodation, the application of the wave theory of light-sensation to the layer of nerve-cells, and to the rods and cones of the retina, have too little space. They may be trite to the connoisseur, but are always fresh food for accurate instruction to those who employ text-books.

The reader will profit by the careful explanation of the visual tests, as shown by letters, figures, and characters. The history of the development of the ophthalmoscope, first introduced in this country in 1854 by E. Williams, of Cincinnati, is given in interesting detail. To the quoted report of Helmholtz's public lecture in 1893 on the invention of the ophthalmoscope, in which credit is given by Professor Helmholtz to Dr. William Cuming, in 1846, and later to Professor Boricke for the assertion and proof that the interior of the eye of mammals and man could be made luminous by reflected light, may here be added the statement made by Helmholtz to the reviewer, that he was led to a practical solution of the definite exhibition of the interior of the eye by the importunate demands of Graefe for an instrument that would enable him to see the details of the fundus in the hitherto unnamed and unexplained diseases of the choroid, retina, and optic nerve.

The surgical chapters are well written and amply illustrated. On pages 410 and 411 are shown eighteen different sections for the extraction of cataract, which are most interesting to the operator and historian. In a few words, it may be said that the trend of ophthalmic surgeons to-day is away from Graefe's linear and modified linear incisions to the distinctly corneal flaps of Stellway and Welker. The author no longer performs extraction of the lens in its capsule in all cases, because he finds the pupillary field is not as free from membrane lens matter as it should be.

Part IV., on refraction, should be read with care. The dependence of asthenopia upon hyperopia to a large extent, as first noticed by Donders fifty years ago, forms the index of the author's argument.

The practical advances made in the study of eye-strain, neurotic asthenopia, ocular reflexes, etc., are entered upon with much detail, illustrated by frequent examples in private and hospital practice. What better and shorter or clearer definition could be given than that contained in these few words: "Spasm of accommodation is excessive tension of the ciliary muscle"?

In connection with this subject of asthenopia is the elaborate work of Dr. A. B. Deynard, who examined the eyes of one hundred persons not suffering from asthenopia, with reference to the existence of corneal astigmatism. He found that astigmatism was a more important element than hyperopia in the causation of asthenopia, and concludes that hyperopic astigmatism, or simple hyperopia, or both combined, are at the bottom of most cases of true asthenopia. These persons never had had asthenopia, and could not be expected to suffer from its well-known symptoms. But they had corneal astigmatism and hyperopia in low degree: none were myopic. The examinations were made with Javol's ophthalmometer, and went to establish the rule that unless corneal astigmatism exceed 0.50 of a diopter, it need not be corrected; also that quite an amount of hyperopia may exist without symptoms of asthenopia. The tables cover eleven pages, and are of great interest in clearing up much that has been uncertain and irrelevant in asthenopia depending on hyperopia; and they go far to confirm the truth of Donder's form-

ula of fifty years ago. To the student of advanced ophthalmology they form the most interesting feature of the book.

In closing this review references must be made to the happy absence of a large array of figures for purposes of illustration, and of a multitude of quotations of disputed and disputable value. If Dr. Roosa has added to ophthalmology it has been on the lines above noted, and by his clear, authoritative style of teaching. Author and publisher are to be congratulated on the text and illustrations.

Local Anæsthetics and Cocaine Analgesia. Their Uses and Limitations. By Thomas H. Manley, A.M., M.D., New York. Member of New York Academy of Medicine, New York Pathological Society, the American Medical Association, the New York State and County Associations, Visiting Surgeon to Harlem Hospital, etc. St. Louis: J. H. Chambers & Co. 1894.

The monograph here presented seeks to fill the hiatus in surgical literature bearing upon the uses of cocaine and the methods by which it can best be employed. Thermal agents in the reduction of pain-sense are also considered.

There are many slight typographical errors which have been overlooked in the proof-reading. These might be passed by without comment, were it not that the peculiar construction of some sentences and ungrammatical use of words indicate a lack of care in the preparation of the work which seems scarcely justifiable in a medical author of the present day. Many useful facts and hints are given in the work to guide one in the employment of local anæsthesia.

Hahnemann's Therapeutic Hints. Collected and arranged by R. E. Dudgeon, M.D. London: E. Gould & Son, 59 Moorgate Street, E. C. 1894.

This little book is designed by its author as an aid in the selection of the appropriate remedy. There is first a list of abbreviations, and then under anatomical or physiological headings the abbreviation indicates the drug, but not the dose.

Transactions of the Colorado State Medical Society. Twenty-fourth annual convention. By-laws and list of members. Denver, June, 1894.

This is a bound volume of nearly five hundred pages, reflecting much credit upon the Society, and containing numerous papers and articles of interest and importance. A paper on tuberculosis among the Indians and others relating to phthisis are found among them.

Transactions of the Medical Association of Georgia. Forty-fifth annual session, 1894. Atlanta, Ga.

Contains an address by the president, Dr. Elliott, and various papers upon medical and surgical subjects. It is neatly gotten up and bound.

Columbia College in the City of New York. Fifth annual report of President Low to the trustees, October 1, 1894.

All the schools are included in the report, but that of the School of Medicine most concerns our readers. The report of Dean McLane makes a very favorable showing.

Higher Medical Education. The true interest of the public and of the profession. Two addresses delivered before the Medical Department of the University of Pennsylvania, on October 1, 1877, and October 2, 1893. By William Pepper, M.D., LL.D. Philadelphia: J. B. Lippincott Company. 1894.

The high plane to which the teaching at Pennsylvania University has reached is now known the world over. Dr. Pepper's book deals with problems connected with the greater advancement of medical instruction. The results of the establishment of a four years' course at the university are given, and this alone must prove of great interest to teachers of medicine everywhere.

Association of Military Surgeons of the United States. The proceedings of the fourth annual meeting, held at Washington, D. C., May 1, 2, and 3, 1894. St. Louis: Buxton & Skinner.

The present is the most pretentious volume ever issued by the Association, containing 816 pages and an index. It is freely illustrated, and many of the pictures, besides being instructive, are attractive in an artistic sense. The work is well printed and fairly well bound, and to those interested in questions of military surgery it is worth the price of four dollars at which it is sold to non-members. It seems a pity that so good a work should be defaced by the advertisement of a proprietary remedy opposite its title-page.

Dissections Illustrated. By C. Gordon Brodie, F.R.C.S., late Senior Demonstrator of Anatomy in Middlesex Hospital Medical School. Part III., Head, Neck, and Thorax. Royal 8vo, pp. 114. London and New York: Macmillan & Co.

The third of these excellent series of vari-colored anatomical plates, containing illustrations of dissections of the head, neck, and thorax, five of which plates are of full size, the rest two-thirds natural size. They are accurately drawn from actual dissections of the author, by Mr. Percy Highley, and comprise views of the different planes and surfaces of the neck, thorax, and head, bringing out the topographical anatomy of the different important organs in striking relief.

Transactions of the American Ophthalmological Society. Thirteenth annual meeting, 1894.

This pamphlet contains the detailed proceedings of the meeting in Washington in 1894. The material, in variety and intrinsic work, compares very favorably with that of previous volumes.

Transactions of the American Surgical Association. Vol. XII.

This volume, although somewhat below the average size, contains the usual number of interesting articles, among which may be mentioned those by Keen on "Amputation of the Shoulder;" "Surgery of the Kidney," by Tiffany; "Surgery of the Ureter," by Fouger; and "Extirpation of the Larynx," by Carmalt.

Manual of Practical Morbid Anatomy. By H. D. Rolleston, M.A., M.D., F.R.C.P., Fellow of St. John's College, Cambridge, and A. A. Kanthack, M.D., M.R.C.P.; Lecturer on Pathology in St. Bartholomew's Hospital. 12mo, pp. 240. London and New York: Macmillan & Co.

This is intended as a practical handbook for the post-mortem room, and contains all that is necessary as a groundwork for the study of the gross pathological changes in the different organs of the body, with the necessary and special directions for their easy demonstration and intelligent study. It is well and systematically arranged, and is full of those practical suggestions so much needed by the hospital interne and, in fact, every practitioner who desires to conduct an autopsy skilfully and intelligently.

Helps in Sickness and Health. By Henry C. Burdett, author of "Hospitals and Asylums of the World." 12mo, pp. 484. London: Scientific Press. 1894.

This work is a *multum in parvo* of hygienic directions and touching every practical point regarding the individual and his surroundings, from the nursery to the grave. The nursery, the school-room, the care of the person, food, and drink; work and rest; the domicile,

its care, structure, and situation; simple ailments and emergencies, and sick-room cookery, all receive an intelligent and masterful treatment from the standpoint of the thoroughly practical and common-sense study of an experienced sanitarian. It is of particular value to the housewife, and to such as live in distant places, out of the reach of immediate help in times of emergency.

A Manual of Modern Surgery; General and Operative. By James Chalmers Da Costa, M.D., Demonstrator of Surgery in Jefferson Medical College. 12mo, pp. 806. Philadelphia: W. B. Saunders. 1894.

This work, as its preface states, is intended to present in clear terms and in concise form the fundamental principles, the chief operations, and the accepted methods of modern surgery. It thus stands between the concentrated compend and the larger text-book. The author has quite successfully carried out these aims, and gives the student and practitioner a first-class work of its kind. He has the happy faculty of condensing general principles into salient facts, and stating in a positively direct way the latest and best rules of practice. In these respects the manual is destined to be of great value to the student whose object is to lay a broad and sure foundation for future work in the surgical line. The illustrations are numerous and to the point.

The Vaccination Question. By Arthur Wallaston Hutton, M.A., formerly Scholar of Exeter College, Oxford, etc. Pp. 128. London: Methuen & Co. 1894.

This little book, having as a frontispiece an illustration of Monteverde's statue of Edward Jenner vaccinating his son, takes the form of a letter addressed by permission to the Principal Secretary of State for the Home Department. The argument has for its scientific basis the observations of Creighton and Crookshank as to the identity of cow-pox with syphilis, and in addition considers at length the various statistics of deaths from small-pox, vaccination, and inoculation. Although nothing of much novelty is presented, the book is written in a style far more temperate than one expects to find in the productions of the "antis." As the best presentation of the other side of the question we commend it to our readers, without, however, expecting that they will find its arguments convincing.

Transactions of the Clinical Society of London. Vol. XXVII., pp. 319. London: Longmans, Green & Co. 1894.

This volume presents many valuable papers upon various subjects, surgical as well as medical. Although there is but little of novelty to be found, many of the contributions contain suggestions which are well worth the attention of the progressive practitioner.

Transactions of the Michigan State Medical Society. Vol. XVIII., pp. 589. Detroit. 1894.

We regard this volume as one which would be creditable to any State society, even if older in years. The discussion upon Tuberculosis is particularly valuable. The papers of Vaughan, Gibbes, Shurly, Novy, and Manton are of especial interest.

Difficult Labor. A Guide to its Management for Students and Practitioners. By G. Ernest Herman, M.B., London, F.R.C.P.; Senior Obstetric Physician to the London Hospital; Physician to the General Lying-in Hospital; President of the Obstetrical Society of London; Examiner in Midwifery to the Royal College of Surgeons; Late Physician to the Royal Maternity Charity. 8vo, pp. 442. New York: William Wood & Co. 1894.

This attractive little volume is written in a concise, business-like way that renders it of considerable practical value. While we cannot approve all of the author's dogmatic statements, we find much to commend. The title is somewhat misleading, as will be evident from a glance at the table of contents, which includes chapters on Rupture of the Uterus and Hemorrhage Before and After Delivery. The keynote is the early recognition and prompt treatment of abnormalities, which is also the central idea in a recent American work on obstetric surgery.

The initial chapter, on the important subject of occipito-posterior positions, is somewhat disappointing, since little is said about those cases of non-rotation in which the reader most needs advice. The rotation of the child by external manipulation is described as "quite easy." We doubt if this will be the experience of even expert obstetricians. Nothing is said about internal rotation or version.

The directions as to the management of breech-presentation differ from those usually given in this country. The author disapproves strongly of the application of forceps to the breech, but is a firm advocate of their use in cases of arrest of the after-coming head by the imperfectly dilated cervix.

Pelvimetry is thoroughly treated, over a hundred pages being devoted to pelvic deformities. We find a brief reference to immediate trachelorrhaphy, an operation with which the author seems to have had but slight personal experience.

In chapter XXV., on the Forceps, we note an extended reference to the "pendulum movement," which is spoken of as "advantageous" (!) The English method of applying them, with the patient on his left side, is the only one described. Dührssen's work (both his multiple incision and intra-uterine tamponade) is damned with faint praise. Figs. 154 and 155, representing the introduction of the uterine sutures in Cæsarean section, are manifestly incorrect, and the description of the operation is hardly in accord with modern aseptic technique.

The short chapter on symphysiotomy is written in a perfunctory way which shows that the author does not share in our enthusiasm over the operation. Fig. 159 is surely not intended for Galbiati's knife!

As we stated before, there is much to commend in the book, and barring a disposition on the part of the author to approve of his own methods only (and those of Barnes), it is terse and practical. Condensation, by the omission of the irrelevant chapters to which we have referred, would add to its scientific value, but even in its present form we commend it to students and practitioners.

A State Medical College for Illinois.—The board of regents of the University of Illinois, located at Champaign, have about concluded negotiations with Dr. W. E. Quine, president of the College of Physicians and Surgeons, Chicago, and its board of trustees, for the purchase of that institution with the view of making it the medical department of the State University. According to Chicago daily papers negotiations have gone so far as to amount to an agreement, all that is yet necessary being an appropriation of about two hundred thousand dollars by the Legislature for the purchase of the college properties, and so confident are the college authorities that this purchase will be consummated that they have already indulged in a banquet over the to them fortunate event. The homœopathists are fighting this scheme because it will give official recognition to regular medicine. They argue, not that it will be injurious to the public good to have a large and well-endowed medical college, but that it will hurt homœopathy.

A License Law for Chiropodists.—In a paper recently read before the New York State Pedicure Society, Mr. C. S. Levy advocated the adoption of a law regulating the practice of chiropody. The suggestion was adopted by the Society, and it was unanimously voted to urge upon the Legislature the passage of a registration law.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Eighty-ninth Annual Meeting, held at Albany, February 5, 6, and 7, 1895.

GEORGE HENRY FOX, M.D., PRESIDENT, IN THE CHAIR.

THIRD DAY, THURSDAY, FEBRUARY 7TH.

Nominations.—The report of the Committee on Nominations was read by DR. E. F. BRUSH. For *President*, Dr. Roswell Park, of Erie; *Vice-President*, Dr. William Maddren, of Brooklyn: *Secretary*, Dr. F. C. Curtis; *Treasurer*, Dr. Charles H. Porter. *Committee of Arrangements*, Drs. W. J. Nellis, William Hailes, Jr., W. J. Morton; *Committee on By-laws*, Drs. H. D. Wey, A. R. Simmons, F. C. Curtis; *Committee on Hygiene*, Drs. Lewis Balch, L. S. Pilcher, D. S. Burr, Z. T. Emory, E. Stoddard, O. W. Peck, Lucien Howe; *Committee on Legislation*, Drs. Seneca D. Powell, Morris J. Lewi, A. W. Suiter; *Committee on Ethics*, Drs. John S. Warren, Charles Jewett, Eugene Beach; *On Prize Essays*, Drs. A. Jacobi, Henry Hun, W. S. Cheesman; *On Publication*, Drs. F. C. Curtis, W. W. Potter, F. D. Bailey, C. H. Porter; *Honorary Member*, Dr. George H. Rhoe, of Maryland.

The committee reported against change of place of meeting, but in favor of the last Tuesday in January as the time. The report was adopted.

THE PRESIDENT appointed Dr. R. A. Witthaus, of New York, to confer with a committee of the State Bar Association regarding abolition of the coroner system.

Clinical Notes on Psoriasis, with Especial Reference to its Prognosis and Treatment.—DR. L. DUNCAN BULKLEY based this paper on three hundred and sixty-six cases of psoriasis seen in private practice. It occurred a little oftener in males than in females, at all ages, chiefly from fifteen to thirty years of age. The disease was essentially chronic, in the cases mentioned having existed five to ten years before the patients consulted him. In one instance it had existed thirty years. The point emphasized was that psoriasis was not a local disease, but depended upon a general condition which produced the eruption again and again. It was closely associated with gout and faulty metabolism. It was benefited by alkaline remedies, counteracting acidity of the blood and urine. Local treatment was only of secondary importance. Psoriasis could and should be cured just as gout, chronic bronchitis, etc., could be cured.

Notes on a Case Illustrating the Treatment of Eczema Capitis by Salicylate of Soda.—DR. C. E. LOCKWOOD, of New York, related a case of eczema of the scalp in a man of rheumatic tendency, the rheumatism disappearing with the appearance of the eruption. This had continued four years when he saw the patient and instituted treatment which included the administration of salicylic acid. The scalp eruption thereupon disappeared. He hoped others would try salicylic acid in cases of eczema in patients with rheumatic history.

In corresponding with Haig on the subject, this gentleman had expressed great interest in the case, and said he would certainly try the salicylic acid treatment in future in rheumatic cases of eczema.

DR. L. D. BULKLEY was glad to hear Dr. Lockwood's paper, as it was practically in line with his own, calling attention to the necessity of treating the patient's general condition rather than the local eruption in certain skin diseases. He had used salicylic acid for years in eczema in cases of rheumatic diathesis, and had written upon it and the use of water as a diluent, and the necessity for eating sparingly of meats, many years ago.

DR. ELSNER said there was a mistaken notion in the profession that, in rheumatism and so-called uric acid diathesis, the trouble was due to excess of uric acid, whereas it was not an excess but retention of uric acid. He believed Haig had been working at the question of uric acid for years, his recent work simply being a review, as it were, of his former writings. Dr. Elsner did not approve of cutting off all meat diet. The point was to see that metabolism went on perfectly, and where it did not the trouble might lie in a cup of coffee, or other like things, instead of in meat and foods which were wholesome for most people.

DR. WILLIAM MADDREN, of Brooklyn, impressed the importance by way of prevention of using water for washing out the system.

DR. BULKLEY explained that he did not cut off all meat in all cases, but he had found an excess at fault in many instances. His paper, he said, was written twenty years ago.

Blood Examinations Regarding the Malarial Origin of Zoster.—DR. JAMES MACFARLAND WINFIELD, of Brooklyn, showed by quotations in the first part of this paper that the etiology of zoster was not at all settled. A nervous influence had often been remarked upon, but the direct cause of the nervous and eruptive phenomena had remained unknown. The occurrence of the disease in patients living in malarial districts had led him to examine the blood for the malarial parasite in seven cases coming under his observation. In three there was unmistakable evidence of malarial poisoning, as demonstrated by the plasmodium malariæ. In another this test had been rendered nugatory by the previous administration of quinine. In some of the others it was probable the malarial parasite would have been shown, had proper examination been made. With this evidence the author thought it could be asserted that malaria might, and did, produce herpes zoster.

DR. H. J. MORTON, of Brooklyn, discussed the paper. He said the occurrence of pain along the nerve preceding the eruption, showed that the nerve was primarily affected. But what was the exciting cause of this inflammation around the nerve? It seemed highly probable that it was a toxic influence in the blood itself. It was known that the poisons of alcohol, syphilis, malaria, etc., often attacked the peripheral nerves. The persistent neuralgias of malarial origin indicated a tendency for the malarial poison to affect particular nerves, and the evidence given in the paper made it probable that the eruption of zoster was due to the same cause.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, December 24, 1894.

EGBERT H. GRANDIN, M.D., PRESIDENT, IN THE CHAIR.

Diseases and Disorders of the Stomach.—Papers upon different divisions of this general subject were read as follows: Dr. Morris Manges, on the "Value of Modern Methods of Diagnosis;" Dr. A. Jacobi, "Medicinal Treatment;" Dr. F. Kammerer, "Modern Surgical Treatment." These papers have already appeared in the MEDICAL RECORD.

Modern Dietetic Treatment.—DR. GEORGE B. FOWLER made some verbal remarks upon this division. He thought he was in agreement with Dr. Manges when he expressed the opinion that modern methods, based upon the use of the stomach-tube, were of limited usefulness. Our patients would not subject themselves to the manipulations essential to elaborate chemical and physical tests. Therefore we had to fall back on diet. The stomach not being the only digestive organ, made the subject more complicated than might be inferred from some modern writings. Dr. Fowler expressed

great admiration for the patience and intelligence displayed by Dr. Beaumont in his study of the process of digestion in the case of Alex. St. Martin, published about 1838. His observations still formed a valuable basis for the dietetic treatment of disorders of the stomach.

The speaker said he was convinced that it was an error to suppose the saliva took an unimportant part in the process of digestion, especially in the conversion of starch. The first step toward correcting indigestion was to thoroughly masticate and salivate the food. When a patient complained, he first ascertained whether any particular articles were known to disagree with him, and these were excluded from his diet. If none, he at once placed him upon a restricted régime, for he could never forget that man, like the lower animals, was originally limited to a few simple articles of diet. Cooks paid more attention to their art than to their science. In view of the immense variety of articles swallowed at one meal, could it be astonishing that there should be so much gastric trouble?

To begin with, Dr. Fowler placed the patient upon a monotonous diet by first excluding fermentative foods—the carbohydrates and fats. He had observed that in New York City turkey and chicken caused more indigestion than almost any other article of food, and these were excluded. He also cut off rich soups, pork, hashes, gravies, pies, ice-cream, malt liquors, champagne, and claret. Claret was the best precipitate for pepsin which could be placed in a laboratory. Raw, not cooked, oysters were allowed; in some instances raw clams. He felt his way with regard to fish, and was very particular about cheese. He allowed beef steak, mutton chops, chopped meat, possibly ham, green vegetables, celery, asparagus without flour gravy, bread sparingly.

Dr. Fowler said he was a thorough believer in washing out the stomach when necessary, but usually the stomach-tube was too violent, and drinking hot water would answer the purpose. He was particular to have his patients drink an excess of ordinary water. If they did not improve under such restrictions, he still further reduced the diet, cutting off those found to disagree. He had achieved some remarkable results in children and old people by boiling farina all day or longer, straining through a fine sieve, keeping on ice, putting some into a glass of milk when used, sometimes adding beef essence.

Dr. Max Einhorn did not believe in using the stomach-tube for diagnosis of all cases of gastric trouble, but in chronic cases it was usually essential, excluding those in which its use might be attended by danger. Combine with chemical analysis physical examination and the history, and one had pretty reliable means of diagnosis. He thought physicians were often too strict in dietetic treatment. He believed in some variety of food. The danger of allowing the patient too little food to live upon was greater than that of allowing too much. Of course, articles should be excluded which were known to disagree. He was also opposed to exclusion of starchy food. The idea of fermentation had been exaggerated. It was only where there was an obstacle to their passage through the pylorus that starchy foods fermented in the stomach, and in that event albuminous foods would also undergo fermentation. If the patient were placed on a one-sided diet, it should only be for a limited time, a week or two at most. Regarding nitrate of silver in ulcer of the stomach, Dr. Einhorn thought a solution could be sprayed as in disease of the throat, by use of the tube introduced to the cardiac end. He did not know why Dr. Jacobi should be opposed to carbonate of soda. He had found benefit from it, especially where there was too much acid in the stomach. Methylin blue had proved beneficial in some cases of cancer under his care.

A Rough and Ready Method of Diagnosis.—Dr. Simon Baruch said he had adopted a rough and ready method of diagnosis between gastric neuroses, gastric catarrh, and other stomach troubles. When a patient came to him with chronic gastric trouble, he directed him to eat a hearty meal, including all things which Dr. Fowler had excluded. After a proper interval he washed out the stomach and learned what articles had not been digested, and these were excluded thereafter from the diet. In gastric neurosis all articles might be fully digested, as in one case related. He cleansed the stomach every day or two as long as might be necessary, and in many instances found the Saulsbury meat diet and hot water beneficial.

Nitrate of Silver for Gastric Ulcer.—Dr. Andrew H. Smith suggested that in giving nitrate of silver for gastric ulcer, whose action depended upon contact with the seat of disease, the patient lie on the back and right side, for the ulcer in most cases was situated in the posterior wall. In anæmia from gastric troubles he gave rectal enemata of defibrinated blood, etc.

Dr. Illoway thought the stomach-tube should be employed in diagnosis in all cases in which the symptoms pointed to disease of the stomach. Without a knowledge of the motility and chemical activity of the stomach we could not distinguish between neurotic or hysterical conditions and disorders due to lesions.

Obscene Medical Literature.—Dr. A. Jacobi offered the resolution passed at the meeting of the Academy of Medicine, December 20th, endorsing a proposed bill to compel the payment of letter postage and use of sealed envelopes for transmission of medical pamphlets and circulars the contents of which were not appropriate for public reading.

The Index Medicus.—Dr. Manges offered a resolution, recommending that the Government accept this publication in connection with the library of the Surgeon-General's office. It was stated that the Government could not do this, but since the information was not positive the resolution was adopted. Dr. Jacobi suggested that this did not prohibit members from subscribing for the publication meanwhile, in order to keep it from suspending.

Therapeutic Hints.

Cauterization of the Nares.—It is important that antiseptic applications be regularly employed after cauterization of the nasal mucous membrane; and that the nostril be closed by cotton for several days whenever the patient is out of doors, to prevent taking cold.—Ingals.

After the Delivery of the Placenta.—

℞ Fl. ext. ergotæ,
Fl. ext. hydrastis canadensis.....āā 15 gm.
Fl. ext. hamamelis virginicæ.....q. s. ad 60 gm.
M. Sig.: Teaspoonful three times a day.

—Syuver.

Emasculation of Criminals.—The surgical unsexing of all criminals convicted of offences that indicate constitutional depravities that are transmissible by heredity is both expedient and practicable.—Boal.

Lung Gymnastics.—Properly conducted lung exercise will aid digestion, increase the desire for food, improve nutrition, increase the weight, add to the vital force, and lengthen life.—Walbridge.

Cardiac Adynamia after or during febrile complaints, or in collapse, hypodermic injection of three grains of caffein citrate.—Sevestre.

Turpentine in Diphtheria.—It must be given in frequent large doses and persisted in as long as there is any chance whatever. A child two years of age will take a teaspoonful every two hours without exhibiting any untoward symptoms whatever. I have given it

in nineteen cases and have had eleven recoveries.—KELLOGG.

Pertussis.—Bromoform, one drop for each year of life, four times a day.—PELICER.

Chronic Rheumatism.—Tincture of colchicum ten drops, one hour before dinner for eight days, then none for a week.—SIMON.

Hæmophilia.—Glycerin extract of the red marrow from the heads of long bones of calves.—MANN.

Eczema.—

℞. Iron peroxide ..... gr. ¾
Bism. subnit.,
Zinc oxid ..... āā gr. xv.
Glycerin ..... ʒ ss.
Rose water ..... ʒ ix.

—HERRKEIMER.

Cerebral Syphilis.—

℞. Metallic mercury ..... 20 gm. (ʒ v.)
Lanoline ..... 5 gm. (ʒ jss.)
Liquid vaseline ..... 35 gm. (ʒ j. 1-4.)

Inject subcutaneously from five to seven centigrammes (gr. ¾). Repeat every fifteen days.

—SACAZE.

Cancer of Stomach.—Potassium chlorate one to four drachms daily.—BRISSAUD.

Dysmenorrhœa.—

℞. Fl. ext. viburnum prunifolium,
Fl. ext. Jamaica dogwood ..... āā 2 gm.
Syrup ..... 50 gm.
Water ..... 140 gm.

Dessertspoonful every two hours.

—COCQ.

Deodorizer in Cancer of Uterus.—

℞. Acid salic ..... gr. vj.
Sod. salicylat ..... ʒ iij.
Tr. eucalyp ..... ʒ vj.
Aq. dest ..... ʒ vj.

Three tablespoonfuls to a pint of water as an injection.

Alopecia Areata.—

℞. Chrysarobin ..... 30 gm.
Colophon ..... 5 gm.
Cer. flav ..... 35 gm.
Ol. oliv ..... 30 gm.

M. F. Stilus unguinosus.

To apply at night and wash off with oil in morning. A night-cap should be worn.

—LEISTIKOW.

Impotency from Excess.—

℞. Ext. damianæ fluid ..... ʒ j.
Ext. canthar fluid ..... ♏ viij.

S. : Teaspoonful at bedtime.

Nervous Dyspepsia.—

℞. Sodii brom ..... ʒ j.
Pepsin sacch.
Pulv. carbo. veg ..... āā ʒ iij.
Aquæ ..... ʒ iv.

S. : Teaspoonful after each meal.

Pulmonary Tuberculosis.—

℞. Ichthyol,
Aq. destil ..... āā ʒ v.

S. : Four drops thrice daily, gradually increased to forty.

—COHN.

Diphtheria.—Sublimation of twenty to forty grains of calomel, according to age of patient, every one, two, or three hours.—WAXHAM.

Valerianate of Amyl.—In 2½-grain capsules every half hour up to five or six doses it is valuable for restraining the pain of nephritic colic and relieving the cystitis, though it has no influence on the calculus.—BLANC.

Summer Diarrhœa.—

℞. Benzonaphthol,
Bismuth salic ..... āā gr. ij.
Dover's powder ..... gr. ss.

To child of two years.

—SOLIS-COHEN.

Eclampsia of Pregnancy.—Hypodermic of morphia followed with five or ten minims of tincture of veratum viride by same method.—PAGE.

Dysentery in Children.—

℞. Muriate cocaine 05
Ergotine ..... .50 (gr. viiss.)
Extr. opium ..... .10 (gr. iss.)
Aristol ..... .25 (gr. iv.)
Cacao butter, q. s.

For ten suppositories. Introduce one every two or three hours.

—ADAMS.

Rickets.—

℞. Phosphorus ..... gr. $\frac{1}{75}$.
Saccharin ..... gr. lxxvij.
Essence lemon ..... ♏ij.
Cod-liver oil ..... ʒ iiiss.

Dose ʒ j.

—GUINON.

Psoriasis of Scalp.—

℞. Hydrarg. ammoniat ..... ʒ j.
Sapo. mollis ..... ʒ iij.
Vaseline ..... ʒ j.

—FEIBES.

Constipation in Infants.—Abdominal massage from three to ten minutes produces as good results as purgatives.—KARNITZKY.

Acute Otitis.—

℞. Ichthyol ..... ʒ ss.
Glycerin,
Distilled water ..... āā ʒ ss.

A few drops in ear three times daily.

—SOLT.

Whooping-cough.—

℞. Powdered belladonna-root ..... gr. ⅙.
Dover's powder ..... gr. ss.
Sublimed sulphur ..... gr. viij.
White sugar ..... gr. viij.

M. Sig.: For one dose from two to ten times daily, according to the age of the patient and the effect produced.

—SÉE.

Ovaritis.—

℞. Sulphate of soda ..... ʒ iv.
Sulphur ..... ʒ j.
Sugar ..... ʒ v.
Essence of peppermint ..... q. s.

S. Teaspoonful at bedtime in a glass of water.

—WINTERNITZ.

Coryza.—Draw up into the nostril from the palm the juice of a ripe lemon.

Neuralgia.—

℞. Exalgin ..... gr. j.-ij.
Spt. chloroformi ..... ♏x.
Aquæ ..... ad ʒ j.

One dose every four hours.

—YOUNGER.

Uterine Fibroma.—Monopolar positive electrolysis is palliative in ninety per cent., and diminishes pain in fifty per cent., but only decreases size of tumor in ten per cent. of cases.—BERGONIE.

Pyrogallic Acid is one of the best applications for psoriasis, but the danger of hæmoglobinæmia makes great care necessary.—NEISSER.

Morphomania.—Brusque suppression of the drug, giving a hypodermic only in case of syncope, strong coffee four times daily, the heart strength being kept up with sparteine two grains, and caffeine ten grains, daily.—VOISIN.

Antiseptic Lavage of the Stomach.—

℞. Sodæ biboratæ ..... ʒ ij.
Creolini ..... gr. iv.
Acid. salicylici ..... gr. xviij.
Thymolis ..... gr. iv.

M. Use with a syphon tube after clear water lavage once a day.

—ROSENHEIM.

Malaria.—Salicinum is a safe and reliable antipyretic, especially in these attacks which exhibit so-

called rheumatic symptoms; it is a perfect substitute for salicylate of soda without any of its dangerous properties.—FORBES.

Djamboe Leaves from the tree whose fruit gives us guava jelly, made into a 5 to 80 infusion or fluid extract, acts as a styptic and stomachic, checking diarrhœa after the third or fourth teaspoonful.—HERGEL.

Appendicitis.—I am frequently called to cases of supposed appendicitis which are really nothing more than instances of acute enterocolitis. Many acute diseases will cause tenderness in the vicinity of the appendix; I have seen this in la grippe. My experience has been that the opium treatment has usually proved harmful.—LESSER.

Diphtheritic Angina.—Potassium permanganate, 1 to 200, applied every two to four hours.—CATRIN.

Trional appears to act particularly well in the cases of insomnia where most other drugs refuse to produce any effect. In primary insomnia, and in the sleeplessness of lunatic and alcoholic patients, it seldom fails. It is spoken of most highly by Collatz in cases of sleeplessness in patients suffering from serious cardiac disease.—BAKOFEN.

Strophanthus, like digitalis, appears to be sometimes of value in cases of alcoholism, creating a dislike for drink which may become permanent.—SKWORZOW.

Consumption.—Theoretically, there is much to fear from the effort necessary to obtain sufficient oxygen in high altitudes, especially in patients who have had hemorrhages. Practically this fear has been proved to be quite baseless, except in those whose disease has advanced so far that there is not enough available air-space left in the lungs for free respiration at any altitude. Altitudes of less than eight thousand feet are only exceptionally dangerous for hemorrhagic cases.—MUNN.

SOME USEFUL PRESCRIPTIONS.

BY GUY C. M. GODFREY, M.D.,

FIRST LIEUTENANT AND ASSISTANT SURGEON IN THE MEDICAL DEPARTMENT, U. S. ARMY; POST SURGEON, FORT WASHAKIE, WYO.

IN my experience in general practice I have found several prescriptions to be especially useful, necessity being the cause of invention. The following is very good for wind colic of infants, and I have used it with excellent results:

℞. Extracti zingiberis fluidi..... c.c. 6 (℥ jss.).
Tincturæ asafœtidæ..... c.c. 12 (℥ iij.).
Aquæ menthæ piperitæ,
Aquæ cinnamomi.....āā c.c. 30 (℥ j.).
Syrupi simplicis q. s. ad..... c.c. 120 (℥ iv.).
M. Sig.: ℥ j. (c.c. 4) t.i.d. in water before meals.

Of course, the practitioner will change the quantities and ingredients to suit each case. It is very hard for an infant to take, but its potency is well illustrated in the following case:

The patient, aged fifteen months, was of good family history with one exception. Her father and his four brothers had all suffered severely with wind colic in their childhood. Whether heredity has anything to do with the disease I do not know, but this little girl suffered with colic from the time of her birth. She slept only about six hours out of the twenty-four, and naturally did not thrive well. She was thin and not very strong. She had not a wasted appearance, but had no "baby fat." She was weaned at four months.

Symptoms.—Severe pain in stomach, no diarrhœa, no vomiting, and no anorexia. Patient ate greedily after an attack. Patient would lie down and squirm during an attack; no fever.

Physical Signs.—Very perceptible tympanites over epigastric region. Patient cried a great deal, and lay with knees drawn up. She would occasionally try to place her parent's hand on her abdomen. Pressure seemed to relieve her temporarily.

Clinical History.—The attacks were frequent and severe, and were liable to come on at any time. The child would seem to be all right for some time, but would become uneasy and irritable. She then began to cry, and the regular symptoms soon appeared. Her diet was changed from time to time, and milk and bottles were sterilized without effect. No medicines seemed to do any good. This had continued for fifteen months when I took charge of the case. Having given the usual remedies without permanent effect, I devised and prescribed the formula above quoted. She began to improve after the first few doses, by belching forth gas at an astonishing rate. Her grandmother termed it "a regular cyclone." She slept well, gained in weight, and her appetite became more regular. Nearly three months have passed, and she has not had an attack since then, although in the interim she has cut several teeth.

The following prescription I have found very successful in the treatment of coryza, hay fever, and subacute or chronic nasal catarrh:

℞. Acidi tannici,
Acidi boraci.....āā .65 (gr. x.).
Cocainæ hydrochloratis..... .16 (gr. ijss.).
Aquæ.....q s. ad 30 (oz. j.).
M. Sig.: Use as a spray.

It forms a white mixture, and is not irritating to the nose or throat. The frequency of its use can be regulated to suit the exigencies of the case. Its action is antiseptic, astringent, and sedative. The following is a case in point:

Mrs. N——, twenty-four years of age, of good mind and will-power, contracted, in the summer of 1892, acute coryza from sleeping in the open air in a hammock, while out on a camping party. The cold resisted treatment and relapsed into a subacute or chronic form, with a number of symptoms of autumnal catarrh or hay-fever. She sometimes drew long strings of tough yellowish mucus from her nose. Dust and the odor of flowers made her sneeze repeatedly and violently. Picking up a wet cloth, bathing, or feeling the slightest draft had the same effect. Dusting, sweeping, or staying in a room being swept were impossible for the same reason. Her nose was often stopped up, and sometimes swelled out on either side of the bridge. She occasionally had pains between her eyes, and continually breathed through her mouth. She occasionally slightly improved, but never permanently. Such was the condition of things when the case came under my notice. Rhinoscopic examination showed hypertrophy of the turbinated bones and an inflamed condition of the mucous membrane covering them. There was a slight deflection of the nasal septum to the right. I examined particularly for polypi rhinoliths and foreign bodies, but found none. I put the patient on tonic treatment and prescribed a spray, consisting of sulphate of zinc, hydrochlorate of cocaine, and water. This was continued for about a week without benefit. I then prescribed a snuff, the ingredients of which were boric acid, bicarbonate of sodium, cocaine, and subnitrate of bismuth. This was very irritating, and had to be discontinued. I then ordered the formula written above to be used as a spray every two hours. The tonic treatment was continued. Temporary improvement began at once, and in three days the patient found she could bear exposure better than before. Within a week the discharge had lessened, the hypertrophy had diminished, and the patient had ceased sneezing. Between three and four months have now elapsed since I took the case, and the patient never sneezes when dusting, sweeping, or bathing. She can smell flowers, pick up a wet rag, and bear exposure without any disagreeable symptoms following. The discharge has ceased, and the patient breathes through her nose habitually.

The following formula I have found very effective in menorrhagia and metrorrhagia:

℞. Extracti hydrasti fluidi ..... c.c. 15.00 (℥ ss.).
Extracti ergotæ fluidi..... c.c. 30.00 (℥ j.).
Strychninæ sulphatis..... gmm. 0.20 (gr. iij.).
Tincturæ ferri chloridi..... c.c. 45.00 (℥ jss.).
Syrupi simplicis .....q.s. ad c.c. 237.00 (℥ viij.).
M. Sig.: ℥ j. (4 c.c.) t.i.d. after meals.

I offer the above prescriptions in the hope that they will be of use to my confrères as they have been to me, and I will be glad to hear personally from any gentlemen of the profession who have had either good, bad, or negative results from their use.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE UNIVERSITY QUESTION—LORD ROSEBERY'S VIEWS—THE OBSTETRICAL SOCIETY AND THE GENERAL MEDICAL COUNCIL—THE CHELSEA HOSPITAL SCANDAL—OYSTERS AND DISEASE—INSANITARY BAKERIES.

London, January 26, 1895.

The university question has occupied much attention during the week. The cry for a teaching university in London has been loud enough for a long time past, and the possibility of reconstructing the existing "University of London," which is in reality only an examining board, has been discussed in all its aspects and with all the bitterness that conflicting interests occasion. It is said the question is now approaching a settlement, and certainly the events of Tuesday seem to indicate that the government is no longer afraid to touch the subject.

Lord Rosebery received three deputations on Tuesday in respect to this university question. One of these was in favor of the scheme recommended by the Gresham commissioners last year, which is in essence a proposal to federate all the educational bodies of London of what may be called academic rank. The other deputations opposed this, though on different grounds. The same day there was a special meeting of the convocation of the university to discuss the scheme, and the opposing parties carried on their rather hot debate for between four and five hours. Eventually a resolution was passed in favor of having but one university, and not two, which involves the acceptance of reconstruction, so as to convert the present university into a teaching as well as an examining body. Whether the scheme of federating the colleges and schools under the shadow of the university will effect this, is another question, and in face of the opposing interests may well give rise to misgivings.

Lord Rosebery admitted that London ought to have a teaching university, and observed that if, as proposed, a statutory commission should be agreed to by Parliament, it would have to be on the lines indicated in last year's report, but still to a great extent unfettered in regard to details.

In reference to the incompatibility between a teaching university and an examining board, which was forcibly urged by one of the deputations, the Prime Minister said he could not admit the doctrine that there is such an essential incompatibility, and intimated that the interests of the empire as well as the metropolis were to be considered. Some of the parties are rather jubilant and talk of the coming bill as though it were an act. Others regard as ominous the warning uttered by Lord Rosebery, that if a bill were introduced it could not pass if it met with any long or obstinate opposition in the House. Unless a certain section of graduates falsify all their threats, there will be resistance, both long and obstinate, so that notwithstanding the jubilations of medical teachers around I would warn them against a too confident assignment of their unhatched chickens. Not that I have any sympathy with the selfish assertion of vested interests, or the absurd fear that the degrees will be lowered in value by diluting the power of cram which has hitherto reigned supreme in the London university. The selfish assertions of these fearful graduates is on a par with that of the Fellows of the College of Surgeons. It is a singular fact that these two sets, who pride themselves on their diplomas, oppose every movement which would render those diplomas more popular and thereby increase the prestige of their corporations.

The Obstetrical Society does not like the resolution of the General Medical Council about their diplomas, and Sir John Williams has sent to the journals quite a whining letter about leading obstetricians being "branded with contingent infamy." They have simply been warned that, whoever in future takes part in the issue of unlegalized diplomas will be liable to have his conduct regarded as "infamous in a professional respect." This is the only sentence the council has power to pronounce, and as the society has had three warnings they had better give heed to the voice of the profession. Some of the officials of the society pretend they have never heard of any objection to their certificates. They must be very ignorant or very deaf to the voice of the general practitioner. For many years I have never heard the subject brought up in medical conversation without the conduct of the society being condemned in most forcible terms. The leaders seem hardened, and nothing short of the action of the council was called for. This action will go far with a large number to make the general medical council more respected than heretofore. While professing to be guided by the highest motives, the society has really let loose on the profession a number of imperfectly educated midwives who, on the strength of the diploma, compete for practice, not only in midwifery but in diseases of women and children. And the leaders who have done this thing hold up their hands in horror when plainly told that such conduct is "infamous." Then they dilate further on their disinterested views, as midwives are not their rivals. Of course not. Consulting obstetricians are not afraid of the competition of midwives, and in their disinterestedness say nothing of the twelve hundred pounds they have obtained by the sale of these diplomas!

The Chelsea Hospital for Women election has been, as I expected, a farce. After taking the opinion of certain consultants, the board of management have disregarded it and re-elected the former staff. A good deal of abuse is being uttered over the conduct of the board, but what else was to be expected? The last news is that the advisory committee have resigned their functions. They ought never to have undertaken to advise a board possessed of such a constitution and such a history. Why eminent consultants should want to "put their fingers into such a kettle" is what "no fellow can understand," unless they wanted to put in their own man or men, and if so the snub they have received is no more than they deserve—certainly no more than I anticipated.

Oysters are still under the ban, not only typhoid but cholera, and other diseases, are suggested as being propagated by the bivalve. Some think lobster and crab also dangerous. Then salads, watercress, and other green food are equally condemned, so no more oyster suppers or lobster salads. And this, too, when Drs. Walsh and Waldo have shown that baking does not kill the bacteria which swarm in a new loaf made in some of the insanitary bakeries of the metropolis. I have for some time only eaten machine-made bread, the product of one of the large bakeries in which the hand is not permitted to touch the bread. This certainly seems to offer an advantage over some of the disgusting details that have been published about certain small bakehouses in poor neighborhoods.

THE MARRIAGE OF SYPHILITICS.

To the Editor of the Medical Record.

Sir: I notice in your last number another letter from Dr. Maine, of Auburn, in reference to the marriage of syphilitics. It would be a great satisfaction, to me at least, Mr. Editor, if the doctor could be induced to present a few definite facts, or at least quote even a single authority upholding the position he takes, instead of dealing entirely in glittering generalities. The doctor says that he has received letters from all parts of the United States giving statistics in regard to syphilis to the third generation, and I doubt not that he would receive an equal number if he had written upon contagiousness of fracture of the fibula. He could scarcely have received one from Keyes, who says, "After the virulence of the disease has been exhausted a man may marry, and should marry;" nor from Taylor, who says, "If possible, it is always well to delay the marriage of a syphilitic person until the end of the second year of infection;" nor from the distinguished French author, Alfred Fournier (whose name the doctor kindly adds to my list), who affirms that "Syphilis is but a temporary bar to marriage." I certainly did not write to the doctor; but why quote farther, as authorities the world over are practically agreed on this subject. If we are to consider tuberculosis and marasm (?) as syphilis in the third generation, the doctor will have no difficulty in sustaining his position, but he must settle that with the pathologists. As for controlling the marriage of syphilitics by legislation, it is absolutely infeasible. When we see the great number of diseases, as tuberculosis, cancer, insanity, and gout, which are more virulent, more tenacious, and with a greater hereditary tendency than syphilis to the third generation, one cannot help surmising that the doctor may have been wrought up to an over-estimation of the necessity for legislating against the unfortunate victims of syphilis, possibly by the perusal of that interesting work of fiction "The Heavenly Twins."

Very truly yours,
W. K. Otis, M.D.

5 West Fiftieth Street.

VAGINAL HYSTERECTOMY BY ENUCLEATION WITHOUT LIGATURE.

To the Editor of the Medical Record.

Sir: I am sorry to see the attempt made to revive the "enucleation of the uterus," or "extirpation without ligature" or pressure-forceps, which might almost be termed slight-of-hand surgery and may, as a method, be characterized as useless, needlessly dangerous, and antiquated.

Claims of priority for this operation make us feel as if we had just awakened from a Rip van Winkle sleep, for they carry us back to the surgery of three-quarters of a century ago: this is the way our grandfathers removed the uterus, before they knew how to apply a ligature in such inaccessible places, but even they soon learned better. This operation, the so-called enucleation, is not difficult, it was performed with general success in early days and under far more unfavorable conditions, in advanced cases of malignant disease, without speculum, ligature, or clamp, without anæsthesia or antisepsis, and is perfectly described in Wenzel's "Diseases of the Uterus," in Langenbeck's "Neue Bibliothek," vol. ii., iv., p. 672; in v. Siebold's "Journal für Geburtshülfe," by Sauter Constanz, 1822; by Dubourg, Paris, 1829; New Orleans, 1846, and in other publications.

The operation[1] dates back almost to the early days of ovariotomy, and was then performed very much as it now is—and under conditions more trying in every sense; most of the work was done with finger and scalpel handle, resorting to the scissors only when necessary to sever more resistant tissues, less frequently to the knife.

Sometimes tubes and ovaries also were removed. The time taken was in one instance twenty-five minutes, in another forty-five, and this operator claims that his next case should not take over ten minutes.

Hemorrhage was not excessive, and the styptic lint and sponge which were held in readiness for an emergency, to tampon in case of bleeding, were not required; but Sauter distinctly says "the ligature was of course out of the question," the parts seemed too inaccessible. Dubourg applied one ligature, and says that it may be used when necessary. Appalling as it seems to remove an entire organ, and an important one at that, without a single ligature, it is yet feasible and easily accomplished. No large vessel enters the uterus deeply; both uterine and ovarian arteries ramify freely and penetrate the organ in numerous small branches, hence we can work in safety if we keep within the outer layer of uterine tissue or close to its surface.

This is the old operation, successfully performed and minutely described four-score years ago, but then called extirpation (which it actually is, though not a ligature was used), and not enucleation: this was approximated by Langenbeck, 1813, who left the peritoneal covering of the fundus with a little of its muscular tissue. Anyone who attempts enucleation proper in the average case, will meet with the experience of my good friend, Dr. Mundé,[1] who could certainly have accomplished it if feasible. But why this operation? why risk even the possibility of hemorrhage when a harmless ligature or pressure-forceps will insure safety?

What is gained? Absolutely nothing; the operation when possible is less rapid, less complete, and less safe than the modern extirpation. In pelvic suppuration with deposits and matting together of tissues, we must of course enucleate more or less, but that is not in question here. Ligature or clamp are, moreover, essential, regardless of the question of safety, for the purpose of limiting the blood-supply and the abnormally increased nutrition.

What is usually called an enucleation is a vaginal hysterectomy as generally performed, with the especial precaution of keeping very close to, and rather a little within, the uterine tissue, especially when larger ramifications of the uterine or ovarian artery are to be avoided, peeling off and tearing the tissues, and cutting only firmer strands which will not yield to such measures.

Let us not dim the bright lustre of American surgery by a return to the primitive methods of 1800, and by representing as the height of perfection the absence of the ligature, which was then but a necessary result of an imperfect technique.

Truly yours,
Geo. L. Engelmann, M.D.

St. Augustine, Fla., January 29, 1895.

[1] The history of the operation is more fully detailed in my paper on The History of Vaginal Hysterectomy. Transactions of the Southern Surgical and Gynecological Association, 1895.

THE INCOME TAX FOR PHYSICIANS.

To the Editor of the Medical Record.

Sir: From all appearances at present, some members of the medical profession in this city and elsewhere, throughout our country, will be called upon soon to render up an account to the Government of their respective incomes for the year 1894, and consequently they would like to have some information as to what the $4,000 allowance is to cover which is stipulated in the law. The pertinent questions are as follows:

Is he allowed under the law his office rent, and if he has a private hospital, such accommodation.

Is he allowed his car-fare, carriage-hire, and if he keeps one, is the mention of his private carriage neces-

[1] American Journal of Obstetrics, January, 1895, p. 66.

sary to the conducting of his professional work. It seems to me that he should be, if corresponding allowance is made for those who are engaged in mercantile pursuits. There are doubtless many other questions of equal importance which should be answered before a just basis of an accounting can be made, but they do not occur to me now. An early answer to these through your journal, will not only oblige me, but many of your interested readers.

SUBSCRIBER.

NEW YORK, January 15, 1895.

Diphtheria	158	39
Small-pox	0	3

How to Abort a Gonorrhœa —Knowing that the acquisition of a clap is a great misfortune, and that it is the sole cause of many and serious complications, I believe in an abortive treatment whenever this promises success. For my own satisfaction I have proven that, if properly carried out, the abortive treatment of clap may succeed, and without danger of aggravating the disease. Given a case of very short standing, where the discharge consists of mucus with some pus-cells, first examine with microscope for gonococci. Having found them and settled the diagnosis, the patient is requested to urinate. Now, take an endoscope of such size as will very easily enter the meatus, and having lubricated with a little glycerine, examine the first half-inch of the urethra by daylight, without inserting the instrument deeper than is absolutely necessary. If no line of demarcation be seen, remove the instrument; wash it, and insert it for one inch, and examine again. Probably, now a more or less distinct line of demarcation can be made out between the diseased anterior part and the deeper healthy mucous membrane. Carefully wipe out with dry cotton on an applicator, and then apply thoroughly by means of another swab a ten per cent. solution of nitrate of silver. The swab must enter the urethra a little farther than did the mandrel of the endoscope, and all parts of the canal from this point to the meatus must be thoroughly touched. No cocaine should be used. The patient must now go to bed and take bicarbonate of soda in ten- to fifteen-grain doses every two hours, drinking water at the rate of one six-ounce tumblerful every hour. The following day the discharge should again be examined, and if gonococci be found, another endoscopic examination should be made. If the diseased area extends deeper than before, it is not worth while to repeat the treatment, but otherwise silver may again be applied. If the germs vanish and then reappear in small numbers a day or two later, the application may be again made. It has been my fortune to try this treatment only twice, but both men were cured so promptly, all symptoms disappearing within two days, that I shall follow this method in other suitable cases. It it is to succeed it must be employed very early, for gonococci make their way rapidly to the deeper parts, von Crippa having found them in the fluid of the œdematous tissues around the frenum five days after the attack began.—Dr. H. Lilienthal, *Boston Medical and Surgical Journal.*

As Others See Us.—"The other day I heard an apophthegm," writes Mr. James Payn, "which left me with a very exalted idea of the gentleman who uttered it. We were talking of the medical profession, and he observed of it: 'There is a great difference between a good doctor and a bad one, but very little between a good doctor and none at all.' The cynicism of the remark was deplorable, but its intelligence was indisputable."

Up-to-date Medical Advertising.—Visitors to Paris will be familiar with the advertisements with which the walls of the *châlets de nécessité* and such-like useful structures are liberally supplied. From a perusal of these they learn that certain diseases can be cured by Dr. X. (dr. Speaks english, *sic*) in a surprisingly short time and with the greatest ease. But it has been reserved for the present year to show us the length to which such effrontery can go. On the drop-curtain of a certain theatre there may now be read, between two other advertisements relating to beer and pinces-nez, the following: "Docteur-Médecin Spécialiste, vingt-cinq années de pratique, de midi à neuf heures du soir." Then follows the address.—*Lancet.*

The Calibre of the American Intestine.—In communicating to the Société de Chirurgie the results of some experiments he had carried out on dogs with Murphy's anastomosis button, M. Chaput made a statement which seems to us to open up a field for speculation, if not for inquiry. Basing his opinion on numerous measurements of the human intestines, the distinguished French surgeon informed his audience that the 27 mm. button is far too bulky for the small gut in general, and especially for the lower end of the ileum. Of the three sizes he prefers that which is about equal to 21 mm. in diameter; it is the smallest and adapts itself to the situation more readily than the others. Now, the questions suggested by M. Chaput's remarks are these: Do American citizens, as a rule, possess more voluminous intestinal tracts than their French congeners, and, if so, how far is cookery responsible for the difference? It is, of course, notorious that French cooking is the best in the world; has this fact any bearing upon the presumably small calibre of the French bowel! Digestion being made easy, so to speak, is it the case that a partial arrest of development has been the consequence? Is there also discrepancy as regards length between the *primæ viæ* of the two nationalities? Savages are endowed with magnificent mouth furniture, and dental decay is sometimes said to be a product of civilization dependent to a great extent upon knives and forks! Has the human race any reason to dread analogous deterioration as a corollary to elaborate cookery? Finally, and by way of closure to these *obiter dicta*, are dainty dishes a physiological mistake?—*Lancet.*

Cycling and Heart Disease.—Sir Benjamin Ward Richardson, in an address on this subject before the Medical Society of London, drew these nine conclusions: "First, cycling, when carried on with moderation, in so far as the healthy heart is concerned, may be permitted or even recommended by practitioners of the healing art. Secondly, in all cases of heart disease it is not necessary to exclude cycling. It may even be useful in certain instances where the action of the heart is feeble, and where signs of fatty degeneration are found, since increased muscular exercise often improves the condition of muscle, and of no muscle more than the heart itself. Thirdly, as the action of cycling tells directly upon the motion of the heart, the effect it produces on that organ is phenomenally and unexpectedly great in regard to the work it gets out of it. Fourthly, the ultimate action of severe cycling is to increase the size of the heart, to render it irritable and hyper-sensitive to motion, the cycling acting upon it like a stimulant. Fifthly, the over-development of the heart under the continued and extreme over-action af-

fects in turn the arterial resilience, modifies the natural blood-pressure, and favors degenerative structural change in the organs of the body generally. Sixthly, a fact that has only been incidentally noticed in this paper is worthy of notice—namely, that in persons of timid and nervous natures (neurotics) the fear incidental to cycling, especially in crowded thoroughfares, is often creative of disturbance and palpitation of the heart, and ought to be taken account of as a piece of preventive advice. Seventhly, in advising patients on the subject of cycling it is often more important to consider the peripheral condition of the circulation than the central. Enfeebled or worn-out arteries may be more dangerous than the feeble heart, and, when connected with a heart that is over-active, are seats of danger. This same remark would, of course, apply to cases where there is local arterial injury, as in aneurism. Eighthly, venous enlargement seems rather to be benefited than injured by cycling, and conditions marked by sluggish circulation through veins are often greatly relieved by the exercise. Ninthly, there are three things which are most injurious in cycling—(*a*) straining to climb hills and to meet head-winds; (*b*) excessive fatigue; and (*c*) the process of exciting the heart and wearing it out sooner by alcoholic stimulants, and the omission of light, frequently repeated, and judiciously selected foods. Lastly, the time has arrived when practitioners of medicine everywhere should make observations for themselves that confirm or confute these observations, and add to them so much more that I of necessity have omitted."

Dr. Ernest Sansom, in commenting on the above, referred to his oration on rapid heart, delivered before the society, and said that he could only recall one instance in a cyclist, and he had met with no instance of irregular heart among riders. He thought the worst form of exertion was the running to catch a train, which produced both irregularity and rapidity of heart-beat. The influence of cycling was decidedly more in the direction of good than in that of evil. As a therapeutic agent in the treatment of actually existing heart disease it was quite in accord with the recommendations of Professor Hirtl, of Munich, who prescribed physical exercise; but he thought cycling had many advantages over climbing, which Professor Hirtl extolled. He looked upon the cycle as an important hygienic and therapeutic agent, and thought it was responsible indirectly for the immense moral improvement noticeable in the track and the era of the cycle.

Behring and the Saint Paul Prize.—It is rumored that Herr Behring's visit to Paris was to assert his claim to the Saint Paul Prize, founded twenty years ago, to be given to whoever found a cure for diphtheria. It has never been awarded. The thousand pounds placed in the hands of the Académie de Médecine has increased by accumulated interest. Many consider that Behring is entitled to it if the value of the antitoxin is established. It is also whispered that M. Dupuy, the President du Conseil, intends offering to Herr Behring the Cross of Commander of the Legion of Honor. If there is any hesitation about taking this step, it is due to political considerations. Perhaps the German Government may not care to see an army surgeon honored by the French Government when he has been left out in the cold by his own.

Transmission of the Infection of Typhoid Fever by Oysters.—In view of the recent epidemic of typhoid fever in Connecticut due to eating raw oysters, the following cases, reported to the *British Medical Journal* by so careful an observer as Sir William Broadbent, deserve notice. Dr. Broadbent says: "I saw on November 12, 1894, with Dr. McCaskie, a young married lady who had been attended, a little more than a month previously, by Sir John Williams in her confinement. Up to the time of the attack, for which I was consulted, she had made a favorable recovery. The precautions against the communication of disease of any kind were more than usually careful. Milk and water were boiled, and the sanitary arrangements of the house were perfect. No other inhabitant of the house was ill in any way. In the course of her convalescence from the confinement she had oysters, and in about ten days later was attacked with typhoid fever of an unusually severe type, with early acute tympanites, which proved fatal. On December 6th I saw, with Dr. Benson, a young gentleman who, three weeks before, had had an attack of influenza. After subsidence of the fever he was kept in his room on account of bronchial catarrh. During this time he partook freely of oysters. The sanitary arrangements of the house were faultless; no other member of the household—a large one—suffered; no other source of the attack of typhoid fever, from which he suffered, could be traced. On November 27th I saw, with Mr. Manley Sims, a gentleman and his wife who had simultaneously been attacked with typhoid fever. The sanitary surroundings were irreproachable; no possible source of typhoid fever could be traced, except that a fortnight before they had partaken of oysters. The simultaneous attack was strong evidence of simultaneous exposure to the poison. One of these cases ran a somewhat severe course; the other, in respect of fever, was mild, but was attended with more than usual gastric catarrh. In the course of our attendance on these cases Mr. Manley Sims gave me particulars of an extremely severe attack of typhoid fever in a child, aged eight years. No other member of the household was affected, and no possible source of poisoning could be traced, until it was ascertained that shortly before the attack the child had eaten twelve oysters at the house of friends of the parents. On November 23d I saw a young married lady who, ten or fourteen days previously, had on two occasions had six oysters with a young married lady of about her own age, a cousin. She had a mild attack of typhoid fever, attended, however, with unusually severe gastric catarrh. Her cousin, who meantime had gone to Italy, also suffered from typhoid fever. On November 19, 1894, I saw, with Dr. English, two young men living in the same house, one being the brother-in-law of the other. The sanitary arrangements of the house were good. No other member of the household suffered. The two young men were engaged together in the City in irreproachable surroundings. They had simultaneously been taken ill with an unusually severe form of typhoid fever. One was moribund at the time of our first consultation; the other, after apparently recovering from the severe symptoms, of which acute tympanites was one, ultimately died of perforation. No cause for the disease could be discovered, except that after visiting a theatre they had had an oyster supper together some ten days previous to the setting in of the symptoms. Early in December I was called in consultation into the country by Dr. Forster, of Daventry, to see a clergyman and his daughter, twelve years of age, both suffering from typhoid fever. The daughter had been attacked a few days before her father. Typhoid fever was an unknown disease in the neighborhood, the sanitary arrangements were those usually found in a large country house. Great attention had been paid to the ventilation of the drains and cess pit. No other member of the household was ill. About a fortnight before the attack they had twice had oysters down from London, which had been eaten by the father and the little girl, no one else having partaken of them.

"Other cases, in which the evidence was equally convincing, have come to my knowledge, although the patients have not been under my care, and I have seen several cases of typhoid fever in gentlemen engaged in the City, their families at home not suffering. On inquiry it has been found that they frequently took oysters for lunch."

Medicine and Meteorology.—The Chief of the Weather Bureau, Mr. M. W. Harrington, has issued the following circular :

U. S. Department of Agriculture,
Weather Bureau.
Washington, D. C., January 2, 1895.

The interest manifested by every class of people in the subject of climate and its influence on health and disease, has determined the Honorable the Secretary of Agriculture, through the medium of the Weather Bureau, to undertake the systematic investigation of the subject. It is hoped to make the proposed investigation of interest and value to all, but especially to the medical and sanitary professions, and to the large number of persons who seek, by visitation of health-resorts and change of climate, either to restore health or prolong lives incurably affected, or to ward off threatened disease. The study of the climates of the country in connection with the indigenous diseases, should be of material service to every community, in showing to what degree local climatic peculiarities may favor or combat the development of the different diseases, and by suggesting, in many instances, supplementary sanitary precautions ; also, by indicating to what part of the country invalids and health seekers may be sent to find climatic surroundings best adapted to the alleviation or cure of their particular cases. The hearty co-operation of the various boards of health, public sanitary authorities, sanitary associations and societies, and of physicians who may feel an interest in the work, is asked to achieve and perfect the aims of this investigation. No compensation can be offered for this co-operation other than to send, free of cost, the publications of the Bureau bearing upon climatology and its relation to health and disease, to all those who assist in the work. Co-operation will consist in sending to this office reports of vital statistics from the various localities. That these reports may be of value, it is evident to all that they should be accurate and complete, and be rendered promptly and regularly. Blank forms of reports have been prepared so as to occasion as little trouble and labor as possible on the part of the reporter, and will be furnished by the Bureau on application. At the very beginning of the investigation it is not possible to outline precisely the channels through which the results obtained will be made public, but it is hoped to publish soon a periodical devoted to climatology and its relation to health and disease. The publication will probably resemble in size and general appearance the present *Monthly Weather Review*, the subject-matter being, of course, different. More detailed information will be furnished on application.

Unusual Malformations of the Brain.—At the meeting of the Association of American Anatomists in New York, on Saturday, the 29th, in connection with the general subject of the Significance of Anomalies, Professor Wilder showed three remarkable specimens from the collection of Cornell University : 1. An adult human brain with a complete interruption of the central fissure. The total number of such cases recorded does not exceed twenty. 2. A sheep's brain lacking the callosum or great cerebral commissure. Several human brains with this defect have been described, but the only other cases with animals are three cats, all in the Cornell museum. 3. A three months human fœtus where the left olfactory bulb, commonly rudimentary, is half as long as the cerebrum, as in most of the lower animals, and contains a considerable cavity. It has long been a belief of Professor Wilder that the olfactory apparatus is primary and of great morphologic importance ; that the recognition of food by the smell was once more essential than reflection upon its qualities. The specimen in question, believed to be unique, suggests the possibility of reversion toward a far-off ancestral type.

Intra-laryngeal Injections.—At a recent meeting of the Royal Medico-Chirurgical Society, Mr. Colin Campbell reported a large number of cases of respiratory disease treated by injections through the larynx, after the method advanced by Rosenberg twenty years ago. The drugs used were generally guaiacol and menthol dissolved in olive-oil and glycerine. The results in many instances were very encouraging.

SOME NEW OBSERVATIONS UPON THE CAUSES, MODE OF ONSET, AND PROGNOSIS OF APOPLEXY.

By CHARLES L. DANA, M.D.,

NEW YORK.

Introductory.—The following paper was read in part before the American Neurological Association at its meeting in 1894, and in part before the Practitioners' Society of New York.

A criticism was made at both meetings in regard to the use of the word apoplexy and the propriety of studying a disease of the cerebral blood-vessels from the clinical standpoint.

It might, perhaps, be more scientific to make the title of my paper "A Study of Disease of the Blood-vessels of the Brain with Reference to those Conditions which Lead to their Sudden Rupture or Obliteration." But to my mind the word apoplexy at once suggests all this, just as the term Bright's disease suggests disease of the kidneys and general vascular and cardiac changes.

By the term apoplexy I mean all those sudden vascular lesions which lead to a "stroke," followed as a rule by some form of hemiplegia. It includes not only cerebral hemorrhage but also cerebral embolism and thrombosis, and it is a clinical term which, like hemiplegia, we cannot do without. It is the capital and often terminal symptom of most cases of severe disease of the brain-vessels, and its onset is a fair measure of the seriousness and progressiveness of such disease. Hence we may legitimately use it as a basis for clinical study, always bearing in mind, of course, that in studying it we really are studying the vascular changes in the brain.

In reviewing the records of my personal experience with cases of apoplexy due to hemorrhage and acute softening, I have been struck with the fact that there were some things in connection with the causation and onset of the attacks which differed from the statements ordinarily made. My interest was sufficiently excited to lead me to go more critically over the records of my cases, and the result has been that I find evidence compelling me to reconstruct some of my views regarding apoplexy. It is often the fact that the common and frequently observed morbid conditions are those about which errors become current; and in regard to the matter of apoplexy I find that many writers have based their statements upon statistics which have been handed down from the now somewhat venerable records of French and English hospitals and from the systematic writers on this subject of half a century ago. In this country, at least, there has not been, so far as I know, any extended critical analysis of large numbers of cases of cerebral hemorrhage or of acute softening. In Lidell's work on apoplexy, which appeared in 1873, the number of published cases and the total number of analyzed cases is very small. Excellent systematic articles have appeared from such writers as Flint, Osler, Mills, Gray, and others. Still many of the statements made regarding the etiology and the onset of apoplexy are not borne out by a study of the records which I have investigated. These records consist of 100 consecutive cases of apoplexy with hemiplegia observed in my clinic at the Post-Graduate Hospital, and 82 cases of apoplexy with autopsy observed in Bellevue Hospital. Of these 82 cases I should add that over thirty came under my personal care and observation. The total number of cases, therefore, which I have utilized for study is 182, of which 100 were non-fatal and 82 fatal. I have attempted to analyze the histories of these cases, so far as was possible, first with relation to the predisposing causes, next with relation to the exciting causes, and lastly with regard to the premonitory symptoms and onset.

Predisposing Causes.—Taking up first the question of the predisposing causes, I will say at once that I do not propose to weary you with unnecessary statistics regarding age and sex, nativity, occupation, etc. In regard to these points I shall simply say that one-third of the cases are in females, and that the special apoplectic age is between forty and fifty years. This is particularly true of the fatal cases, while of non-fatal cases rather more occur between the thirtieth and fortieth year. My figures show also that three-fourths of all adult apoplexy occurs between the ages of thirty and sixty, being pretty evenly distributed between the fourth, fifth, and sixth decades. If one were to leave out syphilitic cases, however, we should find that the most serious decade was that between the fifty-first and the sixtieth year. Finally, after the age of seventy apoplexy is relatively rare and is little to be feared. These conclusions regarding age are in accordance, in a general way, with other experience, and I do not present them here as novel.

Taking hemiplegia as a whole, I find that a very distinct history of syphilis was found in 36 out of the total 100 non-fatal cases. In 4 the attack was due to the puerperium; in 1 it followed typhoid; in 5 the patients worked in lead or were painters; in 1 there was Bright's disease; in 5 there was a severe cardiac trouble; in 5 the patients were drivers and heavy drinkers; in 10 others exposure and heavy drinking were striking elements in the history.

This accounts for two-thirds of the cases, one of these thirds being syphilitic. This fact that syphilis causes one-third of all cases of apoplexy has not, I think, been heretofore brought out, though I feel sure that the experience of neurologists will confirm it.

One may feel that the chances of a stroke are immensely lessened if he has not had syphilis and is not subject to Bright's disease, heart disease, or alcoholism.

The special characteristics of the attacks due to syphilis are that they occur early in life, there being, out of 36, 11 in the decade between twenty and thirty, 13 in the next decade between thirty-one and forty, and 9 in the fifth decade between forty-one and fifty. They occur more often, relatively, in women. The prodromata are frequent. The attacks are often multiple in character, and the pathological condition underlying them is usually a thrombosis and softening. While it used to be taught that early apoplexies were embolic, I believe it would be more correct to say that they are syphilitic, and either thrombotic or hemorrhagic.

We can account now pretty satisfactorily for two-thirds of cases of apoplexy by syphilis, the accidents of labor, heart disease, Bright's disease, excessive exposure, and more particularly intemperance in drinking or chronic alcoholism. If a person has not had syphilis and is not a drinker the chances of his dying of apoplexy

are very greatly lessened. The remaining one-third of the cases has still to be accounted for, and this third includes for the most part, I believe, cases of intracranial hemorrhage, rather than softening. The most important factors here, are heavy eating with insufficient exercise and some congenital tendency to arterial disease due to a gouty or rheumatic diathesis. Excessive mental work does not lead to apoplexy, and brain-workers do not die of this disease unless they are intemperate in eating, drinking, and perhaps in smoking, though on this latter point I feel doubtful. Two of my cases only gave a history of excessive use of tobacco as the sole predisposing cause. It is often stated, and is commonly believed, that one attack of apoplexy predisposes to another, and that a person who has had a vessel broken or occluded is extremely liable to have a second attack within two or three years, but the frequency of repeated attacks seems from a study of my cases to be much exaggerated. Thus out of the 79 fatal cases only 4 had had previous seizures, while out of the 100 non-fatal cases 17 had had previous attacks. This makes the proportion of multiple seizures about eleven per cent., but a closer analysis of the records shows that the majority of the multiple attacks occurred in syphilitics and were of a thrombotic character. I do not think, therefore, that the current view that apoplectic patients are liable to secondary attacks is quite correct. While it is true of attacks due to syphilitic thrombosis and to attacks occurring at an advanced age, it is not so of cerebral hemorrhages of non-syphilitic origin. So far as my experience and records go, cerebral hemorrhages are rarely repeated, and it seems as if in many cases the rupture of an artery changed the vital conditions, as it certainly does the personal habits, so that the apoplexy exercised a conservative influence upon the individual, and actually tended to prolong life. It is, I have no doubt, the experience of many that persons who have had a moderate attack of cerebral hemorrhage may live for many years in fairly good health. The wards of our almshouses and hospitals for chronic patients confirm this.[1]

The age at which multiple attacks begin corresponds with that at which the most strokes occur, that is, from forty to sixty years. The interval between the attacks in my 17 cases ranged from one-half to four years, averaging two and a half years. If a patient, therefore, goes three years without having a second attack he is fairly safe. It may be said in this connection that in most of the syphilitic cases the apoplexy occurs in the second or third year after infection, and it is during this time that the patient most needs watching. Still I have records of cases occurring eleven, thirteen, fifteen, twenty-five, and thirty years after the original infection.

Number of attacks in 83 cases	1
Number of attacks in 10 cases	2
Number of attacks in 6 cases	3
Number of attacks in 1 case	4

Influence of Civilization.—The conditions of modern civilization undoubtedly are tending to increase the number of cases of apoplexy, particularly those due to rupture of blood-vessels. The fact that under better sanitary conditions more people reach the apoplectic age is one cause of this. The gradual lessening of the number of acute infectious fevers and the consequent lessening of mortality from such diseases increases the proportionate number of deaths due to diseases of the arterial system; in fact, the stress of modern civilization shows them more, so far as organic disease is concerned, upon the arteries than it does upon the nervous system. The increased opportunities for indulgence in luxurious modes of living, and in excessive eating and drinking, tend to impair the integrity of the coats of the arteries, and to promote conditions of arterial fibrosis. Already this fact may be demonstrated by the statistics of our great cities, as well as deduced from the known laws of pathology.

I speak, perhaps, with more positiveness that I ought, for actual facts regarding the subject are hard to obtain. This is largely due to the peculiar and now antiquated methods of classifying nervous diseases adopted by all English and American health boards. Deaths from acute lesions of the cerebral blood-vessels are classified as "apoplexy," "softening," and "paralysis." The statistics of a large life insurance company, the Mutual Life, were kindly examined for me by Dr. Marsh, and he states that he finds no especial evidence of an increase in apoplexies. But these statistics are, of course, selected cases.

The vital statistics of the Massachusetts Board of Health show that apoplexy as a cause of death rose from the fifteenth in rank in 1877 to fourteenth in 1881, eighth in 1885, tenth in 1890, and seventh in 1892. The number of deaths per ten thousand from apoplexy, paralysis, and softening is shown here:

Rate per Ten Thousand Deaths from All Causes.

	1860	1865	1870	1875	1880	1885
Apoplexy	1.93	2.08	2.70	2.78	4.19	5.12
Softening	.36	.33	.58	.59	.68	.65
Paralysis	3.26	3.78	4.32	5.43	5.23	5.82

In Michigan the death-rate per hundred thousand population is shown in the following table:

	1871–1875	1876–1880	1881–1885	1886–1890	1891
Apoplexy	5.8	6.6	5.9	7.3	10.0
Paralysis	12.5	16.6	20.6	26.9	27.9

In Rhode Island since 1855 the total number of annual deaths has tripled, the deaths from apoplexy and paralysis have quadrupled.[1]

In New York City the deaths from apoplexy and paralysis have increased from 314 in 1866 and 272 in 1867 to 1,194 in 1892 and 1,171 in 1893.

The deaths from these causes between the ages of twenty-five and sixty-five have increased from 219 in 1866 and 197 in 1867 to 939 in 1892 and 931 in 1893.

Here, too, therefore, the deaths from apoplexy and paralysis have quadrupled, while the total death-rate has increased from about 25,000 to a little over 40,000, *i.e.*, it has about doubled.[2]

With regard to the country as a whole, I doubt if the census statistics will prove of much value on the point at issue. The figures for the last census at any rate are not yet available. Dr. J. S. Billings writes me: "The only data that I can give you about apoplexy are that there were reported 8,040 deaths in males and 6,959 deaths in females. With this should be put the majority of the deaths reported as due to paralysis, namely, 8,554 for males, and 8,016 for females."

The total figures of the decennial census reports show a disproportionate increase in deaths from apo-

[1] Through the kindness of Dr. E. D. Fisher, Neurologist to the Almshouse Hospital and Hospital for Incurables, I have been able to secure statistics bearing on the question of duration of life after attacks of apoplexy followed by hemiplegia in 80 patients. A few of them were cases of hemiplegia coming on in infancy and childhood, and these I have not used in my estimates. The average duration of time among 68 men and women since their first attack was five years (the patients being all still living). Among 74, there were 25 who had lived over five years and 49 less than this time. Fourteen had lived over ten years and 4 over twenty years. The longest period since the attack was thirty-two years. Among the 25 who had lived over five years, 10 had had multiple attacks. Over three-fourths had lived less than eight years, and it might be inferred that this is an average maximum duration of life. It must be remembered, however, that many patients are advanced in life when their seizure occurs, and that the natural decay is a factor in shortening their lives. Among the long-lived cases, the majority (two-thirds) were between the ages of thirty and fifty. The sexes of the long-lived patients were about evenly distributed. There were, among the whole 80 patients, 36 women, and 44 men.

[1] Annual Report of Board of Health.

[2] The figures for New York were kindly supplied to me in great detail by the New York City Board of Health.

plexy and paralysis, but this may be due to imperfections in the earlier statistics. In talking with physicians who have practised many years in the country or small towns I find that they have the opinion that they see more cases of apoplexy than usual.

All these, then, support, in a general way, the view that apoplexy, in its various forms, is increased by the conditions of modern civilization.

Exciting Causes and Mode of Onset.—As to the exciting causes of attacks of apoplexy, some misapprehension apparently prevails. We all know that many fatal cases occur in persons who have been on a drunken spree, and that of all exciting causes of fatal strokes alcohol is the most potent. On the other hand, in my experience very few attacks take place, as is currently supposed, during some especial mental or bodily strain. One case occurred at stool, 1 during coitus, 2 during great mental excitement, and 2 after an epileptic fit. But, on the other hand, 13 cases out of 41 recorded occurred at night as the patient was retiring or during sleep, and I will add that most of these cases were thrombotic and often syphilitic in character. None of my fatal hemorrhages occurred during sleep, and I doubt if arteries really rupture at that time; at least, among the cases of which there are autopsical records, I got no history of an attack coming on during sleep. The elaborate theories which have been promulgated to explain how an artery can rupture during a quiet sleep are, it seems to me, unnecessary. The frequency with which attacks occur in the morning after breakfast, or in the evening, is somewhat noteworthy. Few cases occurred in the middle hours of the day.

The cases of apoplexy which occur after parturition all took place within eight days, and occurred usually in the morning and during some slight physical effort.

Much has been said and written about prodromata of apoplexy. In cerebral hemorrhage, however, prodromata rarely are noted. In many cases, indeed, the patient even states that he felt unusually well just before the attack. In a few instances persistent headache, cerebral paræsthesia, vertigo, disturbance of sleep, and sensations of fulness about the head are described. It is mostly in cases of thrombosis that prodromata are described, and these are sufficiently familiar. They consist of headache, temporary aphasia, vertigo and syncopal attacks, slight temporary hemiplegia, insomnia, a sense of oppression, etc.

The following table gives a summary of some of the facts noted regarding the circumstances of the attack:

TIME OF ONSET OF ATTACKS.

At night:	While asleep	11
	On going to bed	2
	(Ten of these were syphilitic.)	
In morning:	After breakfast	3
	At stool	1
	On rising	6
	After drinking	8
During day:	While at work (syphilitic)	2
	While sitting at home (syphilitic)	1
	While walking (embolic)	2
	While under excitement	1
	After hard exercise	3
	After drinking	1
In evening		6
	(Four were hemorrhages.)	

SUMMARY.

At night, during sleep or sleeping hours	13
In morning, on rising or after breakfast	18
In evening, after 5 P.M.	6
During day	10
	47

Hemorrhages occur in morning oftenest; next in evening; rarely during day or during sleep.

Conclusions.—In concluding I can hardly make a summary of the points I have wished to bring out without going into considerable detail. I wish, however, to emphasize the fact that apoplexy and hemiplegia occurring in early adult life are much more frequently due to syphilis than to embolism, and syphilis is a factor in a third of all apoplexies, at least in large cities.

The apoplexies are increasing in disproportionate frequency, owing partly to the facts: that more people live to the apoplectic age; that there is a larger urban population with all that that implies in regard to the use of alcohol, the prevalence of syphilis, and the greater intemperance in eating and working.

Apoplexy does not especially affect brain-workers if they live temperately, but rather spares them.

The special facts regarding the mode and time of onset of apoplexies are summarized in the body of my paper.

Apoplexy is sometimes a conservative agent, calling a halt to excessive activity and intemperate living and actually prolonging life.

About one-fourth of those stricken with apoplexy die from the attack (hemorrhages being the most dangerous, thrombosis, especially syphilitic, being least so).

The average duration of life of those who have and survive one attack is over five years. The chances of a second attack before the fourth year are always considerable, yet do not amount to fifty per cent., and are inconsiderable so far as hemorrhages are concerned. Thromboses are much more apt to recur than hemorrhages.

These conclusions, based upon my own cases and in part upon those furnished me by Dr. Fisher, may be subjected to revision when further observations have been made, but they seem to me to represent the facts so far as obtainable now.

50 WEST FORTY-SIXTH STREET.

CASE OF UNILATERAL CONGENITAL PTOSIS.

BY MARY PUTNAM-JACOBI, M.D.,

NEW YORK.

IN December, 1894, was admitted to my ward, at the New York Infirmary, a healthy baby a year of age, remarkably well developed in every respect, mentally and physically, with the exception of the defect to be described in the left eye. This seemed smaller than its fellow, a little more sunken in the orbit, and was now partially, now entirely, closed by the fall of the upper eyelid. Not only, however, was the levator palpebræ thus evidently paretic, but the entire orbicularis seemed ill-developed—a fact which itself suggested that the paresis of the levator was due to imperfect development of the muscle rather than to paralysis of its nerve. The eyelid was frequently twitching, and the eyeball often showed nystagmic oscillations; but the vision seemed to be normal, under the simple test of exhibiting an attractive object while the right eye was closed. The active and laughing baby immediately grabbed at such object in a quite normal manner. The pupils of both eyes were equal and reacted normally to light. No other ocular muscle was affected, and the facial muscles were all intact.

This case is quite exceptional in being confined to one eye, for in almost all cases the lesion is bilateral. It is exceptional in being so partial. For a few weeks after birth the child could not open the eye at all, but then it began to raise the lid a little, and now the eye is about half opened. In the majority of cases reported, some of the other external muscles of the eye shared in the paralysis of the levator palbebræ, but the paralysis of the latter muscle exists alone in this case. There is occasional nystagmus, but no permanent strabismus. It is characteristic of all the reported cases that the internal muscles supplied by the motor oculi, namely, the ciliary and the sphincter of the pupil, are intact, and the same immunity is observed in this baby.

Although Gowers, in his "Treatise on Nervous Diseases," and Michel, in "Gerhardt's Handbook," refer in general terms to congenital ptosis, few individual cases seem to be reported. This particular form of congenital paralysis seems to be more rare than paralysis of the abducens.

Armaignac's case[1] related to a child, aged two years, in whom, as in our case, the lid of the left eye was thin and contracted weakly, and its upper segment could be raised only imperfectly. But there existed, in addition to the atrophy of the levator and orbicularis, a complete paralysis of the superior rectus, for the eyeball could not move upward, though it could in other directions. Further, the face was markedly asymmetrical, the left external orbital region was flattened, the skin immovable during crying. The left eye seemed to belong to another child than the right, one that had become emaciated by a long illness.

Moebius[2] suggests congenital syphilis as a cause of this lesion, and relates a case in a girl six years of age, an habitual sufferer from hemicrania. Moebius relates another interesting congenital lesion of an ocular muscle observed in a man aged fifty, also bilateral, but affecting the abducens nerve; and in addition, the facial nerve on both sides was involved, so that from birth the unfortunate man had suffered from double facial paralysis, affecting the orbicularis, and double external strabismus. The condition was, therefore, the reverse of ptosis, as the eyes could not be completely closed.

The author quotes a similar case from Graefe, and another from Chisholm, of Baltimore,[3] and establishes a special morbid entity under the title, "Congenital Facial Abducens Paralysis." He attributes the paralysis to a lesion of the conjoined nucleus of the abducens and facial lesion, which Chisholm defines as an arrest of development.

Schenkel[4] found in a man, aged twenty-six, a combined congenital paralysis of all the external muscles supplied by the motor oculi, and also of the superior oblique, while the action of the external rectus was feeble. The extensive defect was interpreted as a generalized defect of muscular development. Accommodation remained normal.

Tilly[5] describes a case of congenital bilateral ptosis in a boy twelve years of age. The eyes could only be opened by the action of the frontalis and corrugator muscles. This case again was not simple, but the ptosis was associated with paralysis of the superior and inferior recti muscles.

Lawford[6] exhibited at a London ophthalmological society an extraordinary family, where the father and three out of seven children (the second, fourth, and seventh), all presented this defect, bilateral ptosis, with loss of movements of the recti.

The frequency of ptosis as a symptom of adult syphilis has naturally suggested the inquiry whether the cases of congenital lesion should also be referred to such constitutional taint. However, none of the cases above described exhibited any symptoms of syphilis. Our own case was a typically healthy, chubby baby, and always has been so.

According to Mackenzie,[7] ptosis is a rare symptom in congenital syphilis. He himself relates a case where very severe symptoms were manifested at the age of five weeks, and at three years there was an attack of complete paralysis of both upper eyelids, coming on after a keratitis, and cured at the end of a month. This, observes the author, adds one to the short list of affections of the cranial nerves observed in hereditary syphilis. He has only been able to find four other cases.[8]

Evans[1] performed Panas's operation on a child terribly deformed by a bilateral congenital ptosis. There was entire absence of the levator palpebræ muscles, great flattening of the ossa nasi, well-marked epicanthus.

The operation is designed to enable the occipitofrontalis muscle to replace the missing levator palpebræ. For this purpose two horizontal incisions were made, one along the upper edge of the eyebrow, a second at the junction of the eyelid and the orbit. Below this two shorter incisions were then made, one beginning near each canthus and running to meet each other, but stopping at one-third of an inch apart. The inner end of each incision was united with the lower horizontal incision by a short vertical line, and thus a square-shaped flap formed, adherent below. This was freed; the skin intervening between the two horizontal incisions was undermined, then the flap passed up underneath it and stitched to the upper margin of the incision along the eyebrow. By this means the lower part of the eyelid became united with the occipitalis, and could be drawn up by the contraction of the latter. The result was quite satisfactory.

In the case of the baby at the Infirmary, the unilateral character of the lesion, its partial extent, and the possibility, from the previous history, that the imperfect muscles might become a little further developed as the child grew older, all forbade operative interference for the moment.

THE ELECTIVE ACCOUCHEMENT (SO-CALLED ACCOUCHEMENT FORCÉ); ITS ADVANTAGES.[2]

By L. M. MICHAELIS, M.D.,

NEW YORK,

ATTENDING PHYSICIAN OUT-DOOR DEPARTMENT, MOUNT SINAI HOSPITAL.

Confronted with the necessity of selecting an operation by which to induce premature labor, our choice will naturally fall on that one which, while possessing comparative ease of execution, holds out prospects of the best results both for mother and child. That the methods in use up to within a short time have been far from perfect, can be seen from the number proposed, tried, and cast aside as unsafe or inefficient. Thus, among these methods, we have faradization, vaginal and intra-uterine douches, injections of carbon dioxide or air into the uterus, irritation applied to the breasts, irritation of the cervix by means of tents or rubber bags inflated with air or distended by water, detachment or puncturing of the membranes, distention of the vagina by means of the colpeurynter or by tampons, and finally, intra-uterine injections of glycerine and the use of the bougie. Some of these methods are unscientific, others are positively unsafe, and all are either uncertain or tedious. Those most frequently resorted to at present are the introduction of a bougie through the cervix to the fundus, between the membranes and the uterine wall, or the injection of sterilized glycerine into the uterus. A great objection to these methods is, that in both there is no little danger of carrying septic matter into the uterus on either syringe or bougie, with the added danger in the latter of directly infecting the woman by means of imperfectly sterilized glycerine. Nor is the use of glycerine without serious danger to the woman by its toxic action on the blood. Embden[3] gives the history of a primapara, in the ninth month of pregnancy, on whom he used this method for inducing labor because of albuminuria with uræmic symptoms. Shortly after the injection she had an eclamptic seizure, and since the glycerine failed to induce labor manual dilatation of the os and extraction of the living

[2] Read before the Medical Society of the County of New York, January 28, 1895.
[3] Embden, O.: Medical Record, July 28, 1894.

child were performed by Dr. Charles Jewett. After delivery the pulse was very slow, and the urine for about twelve hours was stained with a gradually lessening amount of hæmoglobin. In twenty-four hours the patient was markedly jaundiced and lay in a semi-comatose condition, followed, after six days, by gradual convalescence. The author quotes two similar cases reported by Pfannenstiel, and ascribes the symptoms noted to glycerine poisoning and the disintegration of the blood caused by the drug, citing in support of this theory the experiments and observations of a number of investigators. Moreover, the action of the glycerine is by no means certain, and when we add to a contemplation of its action on the blood and its uncertainty of producing the desired effect, the further dangers of sepsis and air embolus, it can hardly be said to appeal to one as an ideal method of inducing labor.

The introduction of a bougie to the fundus uteri, between the membranes and the uterine wall, is a mode of procedure which may be regarded as the one almost universally employed at the present time. In common with all the other methods mentioned above, the objection obtains to this also that it is very unreliable in its action. It is not of such uncommon occurrence that a bougie is introduced and lies in the patient's uterus with no more effect than if it were placed on her abdomen, and the physician must resort to the introduction of a second bougie to bring on uterine action. The element of time, too, is one which cannot be disregarded ; the bougie is supposed to cause activity of the uterus within twelve hours, yet we are never certain when this will occur till pains actually set in, and in the meanwhile the physician must hold himself in readiness, no matter at what inconvenience or loss to himself, not to speak of possible danger of delay to the woman. Nor is the introduction of the bougie free from accidents. It may curl up on itself in the lower segment of the uterus, and thus defeat its object at the outset ; it may cause rupture of the membranes, leading to a tedious and protracted labor ; it may cause separation of the placenta with its attendant hemorrhage ; and finally, it may cause rupture of the uterus, as in a case reported by Hectoen and quoted by Richard Braun von Fernwald.[1]

Contrast with these uncertain and unreliable methods one which is not only positive in its action, but also certain in regard to time, and comparatively free from danger to both mother and child, and moreover, and by no means an unimportant consideration, a purely *elective* operation.

Before discussing the matter any further, permit me to recall the *modus operandi* to your minds. The operation, as you know, consists of two steps, the preparatory and the operative. In the former we begin by rendering the patient's vagina thoroughly clean and aseptic by the use, first of soap and brush, and then by thorough scrubbing and douching with some antiseptic solution. The cervix is then caught and drawn down by means of bullet-forceps, and sterilized gauze is thoroughly packed into the canal, projecting through the internal os ; this done, the bullet-forceps is removed and the packing is continued in the vagina, until that is completely and well tamponed. The patient is then allowed to rest for from six to twelve hours, depending upon her condition and the necessity for interference. In some cases this tamponade is sufficient in itself to bring on labor ; in the majority, however, it does not, but softens the os and renders it easily dilatable, both by mechanical pressure and by causing uterine contractions to start in through reflex irritation, the patient almost invariably complaining of slight rhythmical pains. We then proceed to the second step of the operation, which we do also without preliminary use of the tampon in those cases in which the os will admit one or two fingers, or in which labor has already commenced and the indication points toward rapid emptying of the uterus, as in eclampsia or placenta prævia. This second step, or the operation proper, is performed as follows : After the patient has been placed on the table and thoroughly anæsthetized by chloroform, which, as Grandin[1] has again recently pointed out, has a tendency to cause the uterine muscle to relax which ether does not possess, the gauze tampon is removed from the vagina and cervix, and the patient once more rendered thoroughly aseptic ; the operator's whole hand is then introduced into the vagina, facilitated by the use of creolin or soap dissolved in ether, and according to the amount of dilatation present, one, or two fingers are passed slowly into the cervix up to the metacarpophalangeal joints when they are fully flexed and very gradually withdrawn ; three and four fingers are successively used in this way, and the whole hand is then introduced, the thumb on withdrawal being flexed inside the other fingers ; after this the hand is again passed in, but on withdrawing it the thumb lies on the other fingers—in other words a full fist is made, and on repeating this a few times the os will be found to be dilated sufficiently for the passage of any ordinary head. The force used must be firm yet gentle pressure, our object being, as has frequently been pointed out, to overcome the spasm of the cervix by fatiguing the muscle, and not to force our way into the uterus at the expense of that muscle's integrity. The child is then extracted either by means of forceps or by version, according to the preference of the operator and the exigencies of the case, and the uterus washed out with the antiseptic solution, and, if so desired, tamponed with sterilized gauze. After-treatment as usual. That care is necessary goes without saying, and the possible objection that more or less grave injury may result by the careless performance of the operation applies no more to this than it does to other operative obstetric interference. A man who is not careful in all procedures, has no justification for performing any. In the thirty-one cases which I have been able to collect—some as yet unpublished—in which this operation has been performed, in only one was there any serious damage done to the uterine muscle, and that, a deep cervical tear, was immediately repaired, and the patient here, as well as in the others, made an uneventful and rapid recovery.

Those not yet reported are as follows :

Case I.—L. F——, X-para, aged thirty-six, six and a half months pregnant ; had been feeling perfectly well until three weeks before I saw her, when she was suddenly seized with hemorrhage from the uterus, for which a vaginal tampon was introduced by a physician. Its removal was followed by recurrence of the hemorrhage, and another tampon was applied, only to be followed by further hemorrhage when it in turn was removed. The bleeding continuing, a second physician was called in, who said that nature would stop the flow, and left the case. A third physician was then sent for, who, seeing the unpromising condition of the surroundings, advised removal of the patient to a hospital ; this she would not sanction. I saw her on the afternoon of August 2, 1894, and found her lying in a blood-stained bed, the hemorrhage having continued more or less constantly for the preceding three weeks. Examination showed the size of the uterus corresponding to between the sixth and seventh months of pregnancy ; the external and internal genitals revealed signs of recent hemorrhage ; the os uteri was high up and tightly closed. While no placental tissue could be felt, and despite the fact that the os was tightly closed, the diagnosis of placenta prævia was made from the history of the case, and, although the general condition of the patient was good, the immediate emptying of the uterus was nevertheless proposed, owing to the fact that the patient was so situated that she could not be under constant observation. Because of the absence

[1] Braun v. Fernwald, Richard : Ueber Uterusruptur. Wien, 1894, p. 18.

[1] Grandin, E. H. : Transactions of New York Obstetrical Society, 1893, p. 376.

of all facilities, the preliminary tamponade was not used. An appointment was made for a later hour, before which time the patient was removed to another and a cleaner room, and other preparations made for the operation. At the specified hour she was placed on the table and chloroformed, the genitals, both external and internal, thoroughly cleansed and rendered aseptic, and the hand introduced into the vagina. The os barely admitted the tip of the forefinger. After the application of gentle, steady pressure for about thirty minutes, this finger was finally introduced, the rest of the operation, consisting of the completion of dilatation, version, and extraction of the child, and removal of the placenta, with irrigation of the uterus, taking about fifteen minutes longer. The placenta was implanted laterally and low down on the right, not quite touching the internal os. The child lived for a few hours after delivery. The patient made an uneventful recovery.

Case II.—C. K——, IV-para, aged thirty-seven, six and a half months pregnant; had two slight hemorrhages before August 2, 1894. On account of a moderate degree of prolapse which she had had since the birth of her first child, and for which she had been irregularly treated, she was carefully watched, and when the hemorrhage first appeared the diagnosis of placenta prævia was made, and the patient put to bed and uterine sedatives exhibited. On August 2, 1894, she had a sharp hemorrhage for which vaginal tampons were applied, and shortly after labor pains set in. During the night she had numerous exhausting attacks of vomiting. On the morning of August 3, 1894, I was asked by Dr. M. Katzenberg, the attending physician, to assist him at the case. When I saw her, though the hemorrhage had ceased, she was in a feeble condition, owing to the loss of blood and the weakness caused by her vomiting; the pulse was rapid and feeble. Vaginal examination showed an os admitting two fingers, covered completely by a centrally implanted placenta. Emptying the uterus by the elective accouchement was decided upon, and, through the courtesy of Dr. Katzenberg, I was enabled to perform the operation. The patient was placed on the table, chloroformed, and the genitals rendered aseptic. Dilatation proceeded very rapidly. It had been my intention to separate the placenta from the uterus on one side, rupture the membranes high up, and, grasping a foot, turn and deliver through the rent thus made and the passageway produced by separating the placenta, but since the feet could be felt presenting, and at the same time the attachments of the placenta were high up in all directions, I perforated the latter and extracted the child through the opening, and immediately removed the placenta and douched out the uterus, which contracted at once and well. The performance of the entire operation took fifteen minutes, and was attended by remarkably little hemorrhage. The child lived for several hours. Mother's convalescence normal.

Through the kindness of Drs. Grandin and Marx I am able to give the following short synopses of hitherto unreported cases in which the operation has been performed by them. By Dr. Grandin:

Case III.—Eighth month. Version. In consultation with Dr. Leo. Indication: Profound maternal exhaustion. Success in three-quarters of an hour.

Case IV.—Eight and a half months. Indication: Flat pelvis. In consultation with Dr. H. L. Collyer. Elective accouchement followed by symphysiotomy. Biparietal of child measured four and a half inches. Success in one and a half hour.

Case V.—Term. Indication: Eclampsia. Success.

Cases VI., VII., VIII., and IX. were hospital cases in which the operation was successfully performed. Unfortunately the details could not be ascertained.

By Dr. Marx:

Case X.—Eighth month. Indication: Complete prolapse of cord, fœtus moribund. Version following ineffectual efforts at replacing cord. In consultation with Dr. S. Kohn. Ten minutes.

Case XI.—Eighth month. Indication: Breech complicated by prolapse of cord with doubtful pulsation. Macerated fœtus removed in ten minutes.

Case XII.—III-para. Eighth month. Indication: Generally contracted pelvis. First labor terminated by craniotomy, child weighing fourteen pounds eleven ounces without the brain. Second child, still-born, after forced version, weighed twelve pounds two ounces. Success in thirty minutes. Living child weighing eight pounds.

In the thirty-one cases[1] mentioned above, in which are included those just quoted, the operation was performed for placenta prævia in fourteen, for eclampsia in five, for pelvic deformity in three, for maternal or fœtal exhaustion in two, for prolapsed cord in three, and in four in which the indication could not be learned.

The danger of sepsis is also minimized by the use of this method, especially in those cases in which the preliminary tampon is used, for the risk to the patient is greatly diminished by the fact that the presence of the hand, the only possible carrier of septic matter, is of comparatively short duration, and that the uterus is at once completely emptied and then as thoroughly cleansed. It appears to me that with a bougie lying in the uterus for a number of hours there is a much greater chance for the patient to become septic, especially if the instrument be in any way unclean, and the possible need of introducing a second necessarily increases the danger to which the mother is exposed.

While the operation of elective accouchement is indicated in all cases in which labor is to be induced, or in which, having begun, its completion is to be hastened, it is in the treatment of puerperal eclampsia and of placenta prævia that its special value lies. It is not necessary for me to call attention to the fact that, when in eclampsia the convulsive symptoms have set in, the sooner the uterus is emptied the more amenable does the condition become to treatment, and the greater is the chance for the patient's recovery. If the state of the patient be such that, while it calls for the induction of labor, immediate interference is not required, if, in other words, she shows signs of impending eclampsia complaining of headache, ocular symptoms, slight muscular twitchings, and the pulse be one of high tension, the preliminary tamponade may be employed, the appropriate medicinal treatment being meanwhile instituted, and then at an appointed time the accouchement may be completed. If the convulsive symptoms are already marked and removal of the fœtus be imperative, the patient is deeply chloroformed and the operation performed in one sitting. Incidentally I may remark that, if after delivery the patient's pulse be of high tension, the vascular pressure may be reduced by permitting her to bleed from the uterus, the hemorrhage being easily controlled by the use of the uterine tampon.

Naturally, no hard and fast lines can be laid down by which the operator can be invariably guided; each case must be carefully studied, and depending upon his judgment, either the preliminary tamponade or the immediate operation used according to the patient's condition. By this method, instead of having thirty per cent. and fifty per cent. for the maternal and fœtal death-rate, respectively, we have it reduced to zero for each in all cases in which it has been performed up to the present time, a result achieved by no other way, medicinal or operative, of treating this condition.

The majority of methods devised for the treatment of placenta prævia have one grave defect in common, in that they regard only the life and safety of the

[1] Harris, P. A.: American Journal of Obstetrics, January, 1894. Grandin, E. H.: loc. cit. Grandin, E. H.: American Journal of Obstetrics, October, 1892. Marx, S.: Medical Record, February 17, 1894.

mother, and pay little or no attention to the preservation of the child. So much is this the case that the fœtal mortality is variously estimated at from 50 per cent. to 83.4 per cent. While the maternal condition must always be of prime importance to us, it is, nevertheless, the duty of the obstetrician never to lose sight of the fact that the unborn child has important claims on his consideration, and that its life must not be carelessly sacrificed. Rupturing the membranes, tamponing the vagina, separating the offending portion of the placenta from the lower segment of the uterus, and version by the Braxton-Hicks method, all these procedures take little or no account of the child. It is true that in the early months of pregnancy the safety of the child does not enter into consideration, but the mother's life, whether early or late in pregnancy, is always imperilled, and that these methods fail to secure a good maternal prognosis may be seen by a glance at the death-rate, which is put by different observers at from seven per cent. to sixteen per cent. In marked contrast to this are the results obtained by the use of the elective accouchement, for in every case in which this operation has been performed the obstetrician had not only the satisfaction of saving the mother's life, but also that of delivering a living child where the pregnancy had advanced far enough for the fœtus to be viable. It is in this condition, too, that the os, owing to the increased blood-supply to the cervix and the consequent softness and succulence of the tissues, is easily dilated, and that, contrary to the opinion occasionally expressed, the danger of lacerating the uterine tissue is even less here than it is in other conditions.

A frequently expressed criticism is that the operation is extremely radical; in comparison with the others mentioned above it is, yet with such results to look forward to, the physician can easily bear the blame of advocating a radical measure, and indeed be proud of the criticism, for he saves both his patients and their children. Judging by these results, it appeals to me most forcibly that in the radicalism of this method there lies extreme conservatism.

In regard to the factor which gives this operation its name—that of election—few remarks are necessary; the advantage of being able to appoint a definite time when the woman's pregnancy is to be terminated, adding in a very marked degree to the value of the operation. Further, instead of being compelled to adapt ourselves to circumstances, and to the surroundings, and thus do our work under greater or less difficulty, we are enabled to arrange the room and prepare the patient to the best advantage to her and to ourselves, so that when we enter the room at the selected hour, we do so with the knowledge that everything requisite has been carefully provided, and that the patient is in a thoroughly aseptic condition; in other words, that she is in every way ready for the obstetrician as she would be for the surgeon about to perform an operation. The contrast between this picture and that of the waiting and uncertainty dependent upon the use of the bougie, is too marked to call for extended comment.

In conclusion, and refraining from touching upon a discussion of the application of this method in cases of accidental hemorrhage, prolapsed cord, contracted pelvis, or maternal or fœtal exhaustion, I will briefly summarize the advantages of this method as follows:

1. It is indicated in all cases in which labor is to be induced, and in many in which labor is to be rapidly terminated, but is of especial value in puerperal eclampsia and placenta prævia.

2. It is not markedly difficult of performance.

3. It is free from danger of traumatism to the patient if ordinary care be exercised.

4. The danger of sepsis is reduced to a minimum.

5. The ultimate prognosis for both mother and child is excellent.

ANÆMIA IN CHILDREN.[1]

By FREDERIC M. WARNER, M.D.,

VISITING PHYSICIAN TO THE NEW YORK CITY HOSPITAL; CONSULTING PHYSICIAN TO THE FRENCH HOSPITAL, DEPARTMENT FOR DISEASES OF CHILDREN, NEW YORK.

By simple anæmia we mean a condition resulting almost invariably as a consequence of previously existing disease, excepting, of course, post-hemorrhagic anæmia, whereby the composition of the blood is greatly altered, resulting in the impoverishment of the vital fluid and the impairment of its function. Should this condition be regarded as a symptom or as a disease? Unquestionably the latter, characterized as it is by certain anatomical appearances and a train of well-marked symptoms.

In children simple anæmia is one of the most important pathological conditions we meet, frequently encountered, complicating many other states, influencing other and grave diseases, always of much significance. In common with the other blood disorders, it is characterized by a diminution in the amount of hæmoglobin, which normally constitutes about ninety per cent. of the bulk of the red cells. The red blood-globules may be only slightly reduced in number, they may even be numerically normal; and in very badly nourished children there is a lessening in the whole amount of blood.

Let us revert briefly to a consideration of the corpuscular elements of the blood, and the relationship of their state or condition to this affection. The red blood-cells are the means by which oxygen is carried to the tissues; they vary in number from four and one-half to five millions per cubic millimetre, in the healthy adult; at birth the number is greater; within a short time it is rapidly reduced.

Nucleated blood-cells, which are normally found in the red marrow, are probably intermediate between the red blood-cells and the marrow-cells; these are not found in the blood of healthy adults, though present in the blood of children up to two or three years of age and in the fœtus. According to Erlich[2] they may be found in the blood of patients suffering from all varieties of anæmia; they are a little larger than the ordinary red blood-cells and contain one or more nuclei.

The white blood-corpuscles are larger and fewer than the red blood-cells in number, being about from eight to fifteen thousand per cubic millimetre normally, although this amount may be greatly increased without affecting the health.

The blood of children contains double and sometimes treble the adult number of white blood-cells, and in exceptional cases even a greater number, and then there is great likelihood that this condition of leucocytosis may be mistaken for leukæmia.

Infants at the breast are said to have present in the blood a greater percentage of leucocytes than those fed on cow's milk. Personally I have not been able to demonstrate this, although I have many times examined the blood of infants for the purpose of comparison. It is an undoubted fact that in all cases of anæmia the amount of hæmoglobin is diminished, the sole exception being in pernicious anæmia, where the hæmoglobin commonly equals or exceeds the percentage of red blood-cells, and this may be demonstrated by means of the hæmoglobinometer, an instrument which, as its name indicates, registers accurately the percentage of hæmoglobin in the specimen of blood. The simplest instrument for practical use is the one devised by Gowers.

In simple anæmia the percentage of hæmoglobin is diminished to a much greater extent than that of the red blood-globules.

In studying any of the blood diseases much may be learned by examination of the blood, 1, for the hæmoglobin, as I have above suggested; and 2, by the microscope, for a determination of the rough proportion be-

[1] Read before the New York County Medical Society, January 28th.

[2] Berliner klinische Wochenschrift, 1880 p. 405.

tween the red and white cells, their color, shape, and size, as well as those of the blood-plaques, the presence of nucleated blood-cells or of foreign bodies such as the *plasmodium malariæ*.

This latter method is simple, and is readily managed by anyone with a microscope with ordinary lenses. For the more exact determination, however, of the relation between the red and white corpuscles special apparatus is required. For this purpose the Thoma-Zeiss hæmacytometer is in common use, and is very simple and easily managed, and consists practically of a slide with a centrally depressed disc, which is divided into microscopic squares. Upon this surface properly diluted blood is dropped, the cells being counted within the given space, and as the dilution is a standard one, the total number of white and red corpuscles per cubic millimetre is easy to calculate.

In various wasting diseases accompanied by great changes in the blood, a condition is sometimes obtained in which marked alterations in the shapes of the red corpuscles occur; they become variously distorted and may even take upon themselves amœboid movements. This is sometimes the case in simple anæmia, but is more characteristic of the condition known as pernicious anæmia.

Etiology.—The causes which lead to the condition of simple anæmia in children are various, chief among them being malnutrition, secondary to graver diseases, such as scarlatina and inherited disease, tuberculosis, syphilis, improper and scanty food, faulty hygiene, including lack of fresh air; and Haig,[1] who has investigated this subject pretty thoroughly, thinks that severe anæmia is sometimes caused by a condition of uric-acidæmia. This I believe to be often the case.

Rachford,[2] as the result of the examination of the blood of one hundred and sixty-six school-girls, has been led to the conclusion that pronounced anæmia without apparent cause is strongly suggestive of concealed tuberculosis, and that anæmia, in apparently non-tubercular girls coming from tubercular stock, is very probably due to a deep-seated and hidden glandular tuberculosis.

Symptoms.—We have seen that in anæmia, 1, the hæmoglobin is reduced, and 2, the red blood-cells may or may not be diminished in number, while the total bulk of the blood may or may not remain practically the same. Therefore, the initial symptom to which our attention is apt to be called in this disease is referrible to this condition—pallor—ranging all the way from almost marble whiteness to dusky yellow; pallor of skin; pallor of all visible mucous surfaces; certain portions of the body become markedly blanched, the ears, nose, and nails.

In some cases the cheeks may be bright red in color while the conjunctiva, the lips, gums, and roof of mouth betray a waxen whiteness. In other cases the temperature is normal, in others an irregular pyrexia may develop, the pulse may be full and soft or small and weak, with the heart's action irregular, while a venous hum may commonly be heard over the jugulars. Leucorrhœa may develop in very young female children and catarrh of the respiratory mucous membranes is of common occurrence.

When the anæmia is secondary to and dependent upon other disease—such as rickets, for example—it is often the first symptom noticed. There is a peculiar puffiness of face, hands, and feet, resembling the œdema of acute Bright's disease. Patients complain of neuralgic pains, the most important and characteristic of which was first pointed out by Flint in cases of so-called spinal irritation, where pressure over the cervical and dorsal vertebræ causes intercostal and cervico-occipital pains, with perhaps the association of nausea, vomiting, palpitation, and a nervous cough.

With these symptoms great weakness and prostration are of frequent occurrence, associated with loss of appetite and obstinate constipation, which latter condition has been believed by Sir Andrew Clark and some other observers to be one of the causes of the disease, by poisoning the patient from absorption of ptomaïnes from the impacted intestinal canal.

Diagnosis.—The diagnosis must be made from chlorosis, pernicious anæmia, leukæmia, beginning pulmonary tuberculosis, and acute Bright's disease.

From Chlorosis.—The age of the patient, as this is an exceedingly rare affection in young children; also the hue of the skin in chlorotic patients is unmistakable, the typical greenish pallor—particularly true of brunettes—being entirely different from the yellow-white or muddy color of simple anæmia.

From Pernicious Anæmia.—A microscopic examination of the blood in this latter condition is essential. The red blood-corpuscles are rapidly reduced in number; they may reach only one-fifth or one-sixth of the normal amount, while on the other hand the percentage of hæmoglobin is relatively high. The red blood-cells are either much larger than normal, or much smaller, and may take upon themselves irregular forms. Nucleated blood-cells are constantly present. The white blood-corpuscles are also diminished, but not to a corresponding degree with the red cells.

From Leukæmia.—In the anæmia of infants leucocytosis is apt to occur, and it is due to this fact that errors in diagnosis are of common occurrence. The composition of the blood, however, is very characteristic. In leukæmia (a rare affection in infants) a constant, steady increase in the number of the white cells obtains, while there is a like steady decrease in the number of red cells. In leucocytosis the number of white blood-corpuscles varies greatly at different times. In leukæmia we have the enlarged liver, spleen, and lymphatic glands, which of course are absent in anæmia, except in a form which has been described by von Jaksch,[1] and which he calls *anæmia infantum pseudo-leukæmia*.

From Beginning Pulmonary Tuberculosis.—By means of the physical signs and characteristic range of temperature.

From Acute Bright's Disease.—By means of the presence or absence of casts and other symptoms marking this affection.

Treatment.—In considering the treatment of this affection our object is primarily to increase the amount of hæmoglobin contained in the blood. When the patient is the victim of inherited disease, syphilis or tuberculosis, medication appropriate to the systemic poison, together with the best possible hygienic conditions—fresh air, abundance of fatty food and expressed beef-juice (the nearest approach to the administration of hæmoglobin at our command), and regular exercise, preferably in the open air—will be of benefit. About the only two drugs which seem to be of efficacy in the treatment of anæmia in young children are iron and arsenic.

Iron.—The blood of man contains about one part of iron to two hundred and fifty parts of red blood-globules. In health a mixed diet contains sufficient iron for all purposes; but when the percentage of hæmoglobin falls below the normal amount, experience proves that the exhibition of iron in many cases promptly arrests this fall and restores the normal balance.

Forchheimer[2] insists upon the intestinal tract as the principal place of origin of the hæmoglobin, and believes that, excluding the origin of anæmias, the reduction of hæmoglobin is due to either diminished formation, excessive destruction, or both. Therefore he treats all cases of simple anæmia, characterized, of course, by a lessening of the amount of hæmoglobin, by intestinal antiseptics. I believe that anæmias of intestinal origin, such as undoubtedly exist, may ration-

[1] Uric Acid, p. 218.
[2] Transactions of the American Pediatric Society, 1892.

[1] Annals of Universal Medical Science, 1890, vol. ii., pp. E. 12.
[2] Anæmia in Children. Transactions of the Pediatric Society, vol. v.

ally be treated on this principle, but only those. The same observer believes that the good effect obtained by the employment of iron in anæmia is partly due to its ability to prevent the formation of albuminous products not compatible with hæmoglobin formation. Be this as it may, the good effects produced in the treatment of anæmia with iron is too old a story to repeat, except to emphasize the fact of its value with a word of caution against its abuse. I believe that the best effects are obtained by the administration of small doses, for in this way it acts in the double capacity as a stomachic tonic and a blood reconstructive. In large doses it quickly exhausts the gastric glands by overstimulation, and it is then, of necessity, discontinued.

Arsenic, in combination with iron or alone, in proportionately larger doses than adults will bear, is of great importance, and especially useful in chronic cases. It acts by increasing the appetite, promoting digestion, and improving the body nutrition. In the anæmia of the uric-acid condition—which is, although of frequent occurrence in young children, commonly overlooked, and which may have resisted iron given in the usual way for a long time—brilliant results will sometimes be obtained by the administration of the salicylate of soda.

Caillé[1] has published statistics regarding the value of the employment of inhalations of nascent ozone in the anæmia of children, which he deems considerable. I have used oxygen in a number of cases, and believe that it has been of service. Exercise in the open air, regularly, is probably equal in value with either. The treatment is therefore thus summed up: Relieve, if possible, the constitutional cause of the anæmia; in addition, give iron and arsenic sparingly, in tonic doses, plenty of good nutritious food, and systematic exercise in the open air.

56 West Fifty-sixth Street.

OBSERVATION ON THE PRESENT EPIDEMIC OF GRIPPE.

By ANDREW H. SMITH, M.D.,

PHYSICIAN TO THE PRESBYTERIAN HOSPITAL, NEW YORK; PROFESSOR OF CLINICAL MEDICINE, NEW YORK POST-GRADUATE MEDICAL SCHOOL.

It is interesting to look back over the annual visitations of grippe since its first appearance in 1889, and to observe the changes of type that have occurred from year to year. At first, the respiratory conditions prevailed almost exclusively, but presently an abdominal form became frequent, and ere long cases were observed in which the nervous system seemed to bear the brunt of the attack. Before the close of the second epidemic these several types—respiratory, abdominal, and nervous—were pretty generally recognized, and were sufficiently distinct to serve roughly as a basis of classification. By the third year the severity of the disease had greatly abated and the types became less characteristic. But each year there has been some peculiarity which, though not entirely new, has assumed especial prominence.

During the latter part of last year's epidemic, a purely tracheal cough became a leading feature in a large share of the cases under my observation. This cough was very persistent, and continued after all the other symptoms had subsided. The irritation by which it was provoked was not, however, very severe; it simply excited the dry, teasing cough, which was the only thing the patient complained of.

This year the same cough is present, but in addition to it there is a positive sense of soreness and discomfort in the trachea. It is often described as a burning or a pricking sensation which is not relieved by coughing, unless the cough results in expectoration, when the irritation will subside for a brief period. It seems to the patient as if the mucous membrane were dry, and as if this condition were relieved when the surface was moistened by the mucus coughed up. This has been verified in a number of these cases by my associate, Dr. W. F. Chappell, who has found, by laryngoscopic examination, that the tracheal mucous membrane was dry and of a deep-red color, and the follicles on the posterior wall were enlarged and prominent.

Another peculiarity, more marked this year than I have seen it before, is the occurrence of subnormal temperature after the subsidence of the febrile stage. This I have observed in a large proportion of the cases under my care. It is often well marked when the previous increase of temperature has not been great, and when the constitutional disturbance has not seemed to be sufficient to account for it. It is not due to the use of antipyretics, for it occurs in cases in which they have not been given, or after their use has been suspended for several days. It suggests the possibility of a production of secondary toxic material having an action upon the heat-centres directly opposite to that of the poison which was present at the beginning of the attack. This subnormal temperature may persist for a week or more, during which time there is no other evidence of disease, unless it be a feeling of lassitude, with more or less mental depression, and perhaps an excessive amount of phosphates in the urine.

Otitis media, with or without rupture of the drum-membrane, seems to me to be much more frequent than in former epidemics.

In regard to treatment, the use of some one of the coal-tar antipyretics during the first stage, to relieve the pain, still seems to hold its place. I have tried to guard against the depressing effects of these agents and to check their tendency to produce excessive sweating; the first, by employing only moderate doses and by adding a little camphor; the second, by the further addition of atropia. A convenient pill is composed of three and a half grains of phenacetin, one-half grain of camphor, and $\frac{1}{300}$ of a grain of atropia sulphate. Two of these pills may be given at the outset, followed by one every three hours until the temperature falls and the pain is relieved.

For the subsequent annoying cough the temptation to prescribe opiates is very great. But they add to the dryness of the tracheal and laryngeal surfaces, and if continued, seem to retard rather than to promote recovery. It is better to employ them only when demanded to procure necessary rest. For this purpose Tully's powder does extremely well. The bromides, by allaying reflex irritability, are very useful. The ammonium bromide, being largely excreted through the lungs, exerts a more decided local influence, and it is at the same time less depressing than the other forms. Yerba santa has done me good service, especially in combination with maltine, for which hot milk is an excellent vehicle.

The mucous surface of the larynx and trachea may be treated locally with advantage by inhalation of warm vapor containing a small amount of carbolic acid. The vapor relieves the dryness of the membrane, while the acid exerts its peculiar anæsthetic effect. Conium also is useful, employed in this way. Maw's inhaler is the simplest and most convenient apparatus for this form of inhalation. A spray of carbolic acid in albolene oil will sometimes produce a more lasting effect than a preparation with water as a menstruum.

When the symptoms of toxic infection persist day after day, I think I have derived distinct advantage from diuretics, reference being had to the condition of the urine in the selection of the agent employed.

If the temperature is subnormal, and especially if phosphaturia be present, I find the mineral acids, with nux vomica, of great service.

The importance of avoiding exposure during convalescence cannot be too strenuously enforced. In every case in which serious complications have arisen under

[1] Transactions of the American Pediatric Society, 1892.

my observation, they were due to lack of care in this respect. Too great haste to resume business or pleasure-seeking is responsible for most of the fatality of the grippe.

VAGINAL HYSTERECTOMY AND OÖPHORECTOMY AFTER SYMPHYSEOTOMY.

By HENRY J. GARRIGUES, A.M., M.D.,

CONSULTING OBSTETRIC SURGEON TO THE NEW YORK MATERNITY HOSPITAL; GYNECOLOGIST TO ST. MARK'S HOSPITAL; ETC.

In the Medical Record for November 10, 1894, I reported the case of a woman upon whom I had performed symphyseotomy, successfully delivering her of a child weighing ten and three-quarter pounds. I stated that I had seen her two months later and found that she had a waddling gait and a constant pain in the pelvis, which she referred to the three pelvic joints. At the time I could not account for that condition, since there was no mobility in the symphysis, and since the ilio-sacral joints did not show any tenderness. Later developments have revealed the cause of those symptoms, and through a secondary operation the patient has been entirely cured.

In the beginning of December, 1894, the pelvic pain increased so much that she could no longer walk at all. On examination I found an inflammatory swelling in the pelvis of the size of two fists. I made an exploratory transverse incision in the posterior vault of the vagina, large enough to introduce the middle and index-fingers. This revealed a dark swelling covered by the peritoneum. When I seized this mass with a tenaculum forceps, a serous fluid spurted out. I cut into it, and palpated the whole pelvic cavity. On the left side there was found the enlarged ovary which had been felt when she left St. Mark's Hospital, at the end of July. The ovary was five or six times larger than normal, and in a condition of small cystic degeneration. It was very easily drawn down and inspected in the vagina, together with the almost normal tube. Both organs were included in a catgut ligature and removed. On the right side there were felt a finger-thick tube and an ovary of the size of a duck's egg. They were matted together and adherent all over. Guided by the sense of touch alone, the adhesions could be loosened sufficiently to allow me also to pull the appendages of this side down through the opening in the vagina. The ovary being squeezed in a Nélaton cyst-forceps, gave exit to a cheesy mass and to hairs, showing that we had to deal with a dermoid cyst. The appendages of this side were ligated and cut off as those of the other side.

The uterus being considerably enlarged and the patient being annoyed by a cystocele, I next removed the uterus. The incision behind the uterus was continued in front of it, passing about half an inch above the end of the vaginal portion.

The bladder was separated from the uterus with closed, blunt scissors and Thomas's spoon-saw.

The broad ligaments were drawn down by means of a ligature carried over them with Hunter's projecting needle, and seized in clamps. Eight clamps in all were required; besides that it was found necessary to stitch the peritoneum to the mucous membrane of the vagina behind in order to check all hemorrhage.

The omentum and intestine appeared in the opening left in the vagina. They were replaced and a Miculicz iodoform-gauze tampon applied.

The forceps were removed forty-eight hours after the operation. The tampon was removed gradually on three consecutive days. When the last part was removed the omentum came along, but was easily replaced and held up with a strip of iodoform gauze packed very loosely in the wound and changed every day.

The first few days the patient had some fever, the temperature reaching 102° F. On the fifth day it became normal, and remained so afterward.

All pain disappeared on the same day, and the patient was put on full diet. From the end of the first week, vaginal injections with a one per cent. emulsion of creolin were given three times a day. The patient left the bed at the end of the second week; the wound was healed at the end of the fourth. She feels perfectly well and her gait has become entirely normal.

In reporting this case as a sequel to the writer's previous report of the symphyseotomy, he wishes at the same time to call attention to the great value of the exploratory incision in the vagina.

Of late years there is a gradually extending tendency among gynecologists to revert to vaginal operations in many cases which, for the last twenty years, have been treated by laparotomy. The often unsightly scar left on the abdomen; the necessity of wearing a bandage, for which some patients cannot afford to pay; the frequency of subsequent umbilical hernia; the frequently persisting pain after removal of the appendages; the smaller mortality in the severe cases; are strong arguments in favor of the vaginal method.

On the other hand, to begin the operation by removing the uterus, and then take the appendages away, if possible, but to leave them if they cannot be removed, which is often rendered particularly difficult or impossible by the presence of a more or less large number of forceps—according to Péan, who has introduced the method, at least four—that would seem to be rather irrational in cases in which the chief affections are found in the appendages.

By making a transverse opening in the vagina behind the uterus, one can explore the whole pelvic cavity. If not bound down with too strong adhesions, the appendages can even be brought to view. The surgeon can then act according to circumstances, removing one set of appendages or both, or extirpating the uterus besides.

If the surgeon finds that the removal of the diseased organs would be easier by the abdominal method, nothng is lost. He has only beforehand made a good opening for drainage, which he often has to make at the end of his abdominal operation, and which it is much easier to make from below upward than from above downward.

THE COMBINED VERSUS THE SIMPLE EXTRACTION OF CATARACT.[1]

A Study of Over Two Thousand Cases.

By FRANK W. RING, A.M., M.D.,

SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL; MEMBER OF THE NEW YORK OPHTHALMOLOGICAL SOCIETY, AMERICAN OPHTHALMOLOGICAL SOCIETY, NEW YORK ACADEMY OF MEDICINE, ETC.

There seems to be among ophthalmic surgeons a wide diversity of opinion in regard to the superiority of the simple over the combined extraction of cataract. It is for the purpose of convincing the unprejudiced mind that I have tabulated the following results, after much research and many hours of careful work. In order to make a fair comparison between any two methods the element of "personal equation" must be eliminated. To publish one thousand cases from the note-books of any one surgeon would not necessarily prove much, unless the results were in marked contrast. He might be especially expert in that one particular, so superior in manual dexterity and judgment that the average man could not compete with him. Therefore, when I select the results of so large a number of experienced operators I eliminate what I call the "personal equation." As guardians of the public vision, if I may be allowed to use the expression, it is our duty to take advantage of the experience of others, to equip ourselves as thoroughly as possible for our work, to use all possible care, skill, and judgment. In restoring sight to the

[1] Read before the New York Academy of Medicine, Ophthalmic Section, November, 1894.

blind we not only give joy to the recipient, but add prosperity and pleasure to his immediate family and friends, and oftentimes relieve the community of a burden, as every eye has its money value, especially to the State. These observations and comparisons are made from the published results and indications of the following gentlemen: Doctors Agnew, Knapp, Noyes, C. S. Bull, Webster, Gruening, Weeks, Hasket Derby, Panas, de Wecker, Galezowski, Schweigger, Schoeler, Pomeroy, Kerschbaumer, and others, names which are guarantee of good work. The following table comprises the salient points in 1,032 extractions after the combined method (with iridectomy), and 1,123 after the simple method (without iridectomy). 52.5 per cent. were male patients with an average age of 62.2; 47.5 per cent. female, average age 59.5.

These cases have been selected from published reports. I have therefore not deemed it necessary to ask permission of the surgeons for my compilations, but have done them the justice of using extreme care in my work. I would like to call especial attention to one thousand extractions done by Drs. Knapp, Agnew, and Webster, as each individual case was reported. Those by Dr. Knapp were published in the *Archives*, and include his sixth, seventh, and eighth hundred Graefe's, and his first, second, and third hundred simple extractions, selections which in point of fact favor the combined method, as his first three hundred simple are inferior to his later ones. The one hundred Graefe by Dr. Agnew were the last he ever did. The Manhattan series were done by Drs. Webster, Pomeroy, and Ring. In the simple extraction of these one thousand cases we have 3.1 per cent. less loss of vitreous; 0.6 per cent. less iritis; 1.8 per cent. less suppuration; 10.3 per cent. prolapse of iris; with only 2.6 per cent. failures, and an average vision of $\frac{5.2}{10.0}$, an increase of $\frac{2.0}{10.0}$; with perfect successes at 95 per cent., instead of 87.7 per cent. as in the five hundred Graefe. Dr. Knapp's three hundred simple, Webster's one hundred simple, the New York Eye and Ear Infirmary seventy-one simple, and Hasket Derby's one hundred Graefe are choice bits of surgical work. Webster, with a loss of 5 per cent. and 26 per cent. discission, the New York Eye and Ear, with a loss of 1.4 per cent. and only 22 per cent. discission, have a higher average vision than the three hundred cases with 60 per cent. discission and 1 per cent. loss. Dr. Knapp asserts, and with good reason, that he has little or no iritis with the peripheric capsulotomy, but in order to raise his vision he subjects 60 per cent. of his patients to a secondary operation, and one not without danger, as he himself asserts, and also one requiring great tact and judgment. The opponents of the simple extraction offer as a serious objection the decided increase over the combined method in discissions. Webster, with a central T-shaped capsulotomy and a loss of 5 per cent., had in 100 simples 12 patients with $\frac{2}{10}$, 13 with $\frac{2}{30}$, 18 with $\frac{2}{30}$, 14 with $\frac{2}{40}$, 11 with $\frac{2}{50}$, 12 with $\frac{2}{70}$, 4 with $\frac{2}{100}$, and 7 with $\frac{2}{200}$.

I am sure Dr. Knapp with his vast experience feels justified in continuing his peripheric capsulotomy, and in his later operations the average vision may be raised above the series in question. We are all aware that a secondary operation increases the vision to a marked extent. In his third series the average vision in 53 cases was $\frac{3.1}{10.0}$; after discission it was $\frac{6.7}{10.0}$, but in a number of his cases which had iritis I found the average vision to be $\frac{2}{30}$. Webster, with 18 per cent. iritis and 26 per cent. discission, had $\frac{5.9}{10.0}$ average vision, showing that a large percentage of iritis does not materially lower the ultimate visual result.

In the second half of the 1,000 Graefe I have selected the best results obtainable in large series; 100 by Hasket Derby, 232 by Schoeler, and 200 by Kerschbaumer. In the second half of the simple series there are 71 by the New York Eye and Ear Infirmary, 235 by Schweigger, 317 by Schoeler. The average results of the entire number of cases cited (2,115) are surprisingly similar to the 1,000 cases already alluded to.

Advantages of the Simple Extraction.—It is only necessary to prove by statistics that the results are equal, or nearly so, to establish its superiority over a method which mutilates and more or less disfigures the most pleasing feature of the face. Let us observe from the preceding statistics what the advantages are: Less loss of vitreous by 3 per cent. I have given the average vision with loss of vitreous for the benefit of those surgeons who maintain that "a loss of vitreous does not matter much anyway." It does matter a great deal, the vision is $\frac{2.0}{10.0}$ less, besides the danger of detachment of retina later on. Less iritis by 1.33 per cent. Less suppuration by 0.61 per cent.—a great gain, when you take into consideration the small percentage by loss in either method. Less total failures by 1.59 per cent. More perfect successes by 2.8 per cent. Greater average vision by $\frac{1.4}{10.0}$; less occurrence of plastic iritis; less frequent incarceration of foreign matter in the wound; no mutilation of the eye; a less strong lens required by from two to three dioptrics. The eccentric vision and orientation are much better, which is a great comfort and safety to the patient (Noyes). No hemorrhage into the anterior chamber.

Prolapse of the Iris.—The *bête noir* of the simple extraction, against which we place in the combined method mutilation of the iris and incarceration of foreign matter in the wound. We do have prolapse of iris in the combined method, and yet in the 1,032 cases no mention was made of it. I am sure it must have existed. In some of the series incarceration of iris was not mentioned. I doubt if a hundred consecutive Graefe's was ever done without a single incarceration. So we really cannot draw a fair comparison between the prolapses in the simple and the incarcerations in the combined method. However, from the data which I have presented the prolapses exceed the incarcerations by 3.84 per cent.

Cause of Prolapse.—I think I may safely say it is most frequently of traumatic origin; self-inflicted, consciously or unconsciously. It may be due to violent straining at stool. The larger the section the more lia-

bility to prolapse. The more peripheric the section the greater danger of prolapse. The roller bandage too tightly applied ; a downward inclination of the eye after expulsion of the lens.

Prevention of Prolapse.—Free the section from all foreign matter, bits of cortical, or lens capsule ; make a corneal section ; an iridectomy when indicated ; rest and quiet, especially for the first forty-eight hours, as the prolapse usually occurs within that time, rarely a few hours after the operation. If the eye is opened within two days do not allow the patient to look down. A mild iritis is rather inclined to prevent a prolapse by its adhesions. Eserine half to one grain to the ounce, applied immediately after the operation, or pilocarpine, two per cent. solution, tends to contract the iris. There is a diversity of opinion in regard to eserine. We have had better results and less prolapse from its use at the Manhattan. Eugene Smith gives a hypodermic injection of morphia after operating, followed by another in eight hours. De Wecker recommends that after simple extraction the anterior chamber be syringed with a solution of eserine.

Preparation of Patient.—Attention should be given to the following conditions : disease of the urinary organs, alcoholism, diabetes, and uric acid dyscrasia, syphilis, chronic suppuration, and articular rheumatism. The patient should certainly be required to enter the hospital a day previous to the operation, in order to get accustomed to his surroundings and relieve his mind of that nervousness and fear which elderly people are liable to have under the circumstances. I have the nurse wash the face with soap and water, cleanse the lids with a solution of bichloride, apply bichloride vaseline, and bandage the eye the night previous to the operation.

Indications for Iridectomy.—Swollen lens ; complications ; danger of prolapse of iris from pressure of vitreous ; in the debilitated ; iritic adhesions ; atrophy of iris ; after the section when a traumatic iridectomy has been done, or the iris bruised or cannot be replaced ; after prolapse of vitreous ; small corneal section ; fluidity of vitreous, and immature cataract. Notwithstanding all these indications it is exceptional when an experienced surgeon will feel disposed to make an iridectomy.

Section.—The peripheric linear section cannot be made in the simple extraction, it tends to prolapse of the iris and iridocyclitis ; therefore it is necessary to go nearer the apex of the cornea, away from the ciliary processes ; consequently it must be made larger in order to admit of the escape of the lens by the iris without bruising it too much. Noyes includes in his section nearly half of the cornea for this very reason. C. S. Bull makes his section entirely in the clear cornea, and rarely ever has a prolapse. Galezowski reports one prolapse in two hundred cases. A corneal section heals slowly and is liable to leave a grooving ; a too large section invites prolapse. I think the circular-marginal of de Wecker advisable. Panas makes the puncture and counter-puncture in the limbus (1886).

Dr. Gruening has made a large number of recent simple extractions without any prolapse of the iris, which he attributes to the fact of having used a ten per cent. solution of cocaine immediately after the operation, probably from the hypotynus which it produces ; and yet we have eminent authority assuring us that cocaine retards the union of the wound. However, we can sacrifice a speedy healing of the section to a freedom from prolapse of iris.

In making the section, pass the knife slowly across the anterior chamber until the point just approaches the limbus, when you depress the handle and make the counter-puncture, immediately proceeding quickly until you get well by the pupillary margin of the iris ; then make your departure slowly. I see no need of rushing quickly across the anterior chamber and making a counter-puncture at haphazard ; very little or no aqueous is lost until you begin the incision ; then by a quick movement, cutting with the heel of the knife as you draw it toward the temple, a traumatic iridectomy will seldom happen.

Capsulotomy.—I think the T-shaped incision preferable. It seems to me the peripheric capsulotomy retards the expulsion of the lens, makes it more difficult to clear the anterior chamber of cortical, and tends to greater danger of loss of vitreous, besides increasing the secondary operations. In expulsion of the lens make your pressure from the lower fourth of the cornea toward the centre of the globe, which serves to tilt it by the iris with less bruising ; make a steady pressure, not intermittent; if the lens sticks a little, counter-pressure from above relieves it from the overlapping iris. This expulsion of the lens is a delicate matter in the simple extraction, as you may get loss of vitreous. The iris usually returns to its normal position ; if not, close the lids and make gentle massage over the cornea, or if still perverse replace carefully with a thin spatular. A too liberal use of bichloride (1 to 5,000) has produced staining of the cornea (Knapp). Cocaine produces hypotynus (under tension), making it a little more difficult to expel the lens, but less liability to prolapse of iris ; it also delays the union of the corneal section proportionately to the strength of the solution and quantity used. "The cause lies in the action of the cocaine on the elasticity of the cornea, and also in the absence of lymph in the parenchyma which the cornea contains" (Mellinger). I think one drop of a four per cent. solution every five minutes up to three instillations quite sufficient. Gruening applies the same every two minutes, three instillations. Noyes is careful to turn the upper lid and apply cocaine to its surface as he very skilfully uses a strabismus hook under the lid to raise it while expelling the lens and making the toilette.

Dressing.—I have usually employed the roller bandage, but am inclined to discard it, especially in the summer. It is easily disarranged, and unless carefully applied makes too much pressure. I now use a wad of bichloride gauze and cotton adjusted with adhesive strips, over which, or any other dressing, at the Manhattan, we invariably place Ring's ocular mask, and since its introduction have undoubtedly had less cases of prolapse of iris. Exponents of the one-eyed dressing must show better results before their innovation will be considered. There seems to be a tendency in certain sections to make the extraction of cataract an office operation. Such a tendency is pernicious and should be discountenanced by all conscientious surgeons. How shall we treat prolapse of iris? Not infrequently a roller bandage will restore it. It may be abscised at the end of twenty-four hours, or it may be left for two or three weeks. The only eye I ever lost from extraction I cut a prolapse twenty-four hours after operating. It is a very unpleasant occurrence, and always causes astigmatism.

Discission is usually a safe operation under thorough asepsis, a good light, and care to cut the places of least resistance. It may be done from two to three weeks after the extraction, depending upon the condition of the eye. Not only from the statistics which I have had the honor of presenting to the Society, but from our personal experience, I think we are justified in maintaining that the simple method of extraction is by far superior to all others in the very great majority of cases. While it is a somewhat more difficult operation than that by the combined method, yet I believe any experienced surgeon will find his results proportionately greater.

Progress of Medical Science.

Tight-lacing and Gall-stones. — According to Dr. Marchand, the relation of tight-lacing to the development of gall-stones is rendered very clear by noticing the situation of the gall-ducts in the liver deformed by tight-lacing. The furrow caused by lacing runs directly across the right lobe of the liver, as the result of which there is a tendency to atrophy of the gall-bladder. When tight-lacing has been practised to an extreme degree, an artificial fissure is formed in the liver, giving rise to what is termed the "lacing-lobe," which carries with it the gall-bladder. The constricted portion of the liver is found to be just at the point of junction of the gall-bladder with its duct. In these cases, according to the author, it is common to find the gall-bladder greatly distended, extending far beyond the border of the liver, and frequently an examination made post mortem reveals the presence of gall-stones. Stagnation of the bile is well known to be one of the most important causes of the formation of gall-stones. A change in the composition of the bile, from catarrh resulting from congestion of the mucous membrane and the thickening of the bile due to failure of the gall-bladder to completely evacuate itself, gives rise to the formation of small masses which serve as nuclei for calculi; hence anything which obstructs the free outflow of bile through the cystic duct must favor formation of gall-stones. Marchand is also of the opinion that many cases of cancer of the liver should be attributed to tight-lacing. It is only a few years since Langenbuch was obliged to open an abdomen to remove a "lacing-lobe" of the liver which had been so completely separated from the rest of the organ as to cause its death, rendering its removal necessary. In view of such facts as these, it is the duty of every physician to take special pains to warn his patients against the evil effect of this pernicious practice. Few women are conscious of the fact that they are injuring themselves by tight-lacing. But physicians generally preach to deaf ears in an audience composed largely of votaries of fashion.—*Deutsche medicinische Wochenschrift.*

The Surgical Treatment of Diffuse Septic Peritonitis. —At a recent meeting of the Royal Medical and Chirurgical Society of London (*The Lancet*), Mr. C. B. Lockwood read a paper on the "Surgical Treatment of Diffuse Septic Peritonitis," and related some successful cases. The communication began with the remark that the term "diffuse septic peritonitis" probably included several kinds of disease. In the variety referred to by him the inflammation was acute and had no definite limits; the serous membrane was smeared with lymph, which was either transparent and oil-like or collected in ashen-gray fibrinous flakes. Adhesions were absent, or very slight; the peritoneal cavity contained thin purulent fluid, which often had a fecal odor, or it might be full of gas; the intestines were distended and paralyzed, and the disease ran a rapid and fatal course. Although cases which came within this definition were numerous, surgical literature contained few records of recovery after operative intervention; authorities were quoted to support this statement, and it was said that there had hitherto been no successful case in St. Bartholomew's or the Great Northern Central Hospitals. It was proposed to include in an appendix the successful cases which others had recorded. Hitherto, Mr. Lockwood had operated upon cases of diffuse septic peritonitis more because he was afraid of overlooking a mechanical obstruction than in the hope of curing the peritonitis. A case was described to illustrate the importance of intestinal paralysis and distention in causing the fatal ending. Stress was also laid upon exhaustion and collapse as factors. In his successful cases a systematic attempt was made to meet exhaustion and collapse by stimulating the patient temporarily before the operation with strychnine and brandy, by the systematic application of warmth during the operation, and by rapid and methodical operating; and by warmth, stimulants, and nutrient enemata afterward. The organization of the operation was described, and the treatment of the distended intestines alluded to. To empty them, the gas was drawn from each coil by puncturing it with a fine trocar and cannula; the fæces were let out by an incision, which was afterward closed. The abdomen was afterward irrigated, and closed after the insertion of a drain. Two cases of diffuse septic peritonitis were described in which the treatment was successful. In the first there was a perforation of the ileum. The peritonitis was of not less than forty-eight hours' standing. In the second case the peritonitis had probably been in progress fifty-two hours. The abdomen was full of free gas, with the usual lymph and purulent fluid. The cause was thought to have been a septic inflammation of the left Fallopian tube. The patient was now convalescent, the operation having been performed more than five weeks ago. A third case was described, in which the peritonitis was diffuse but different in type. In this the recovery was mainly attributed to an accidental fecal fistula, which discharged and prevented distention and paralysis after the laparotomy.

The Kidney of Pregnancy.—Dr. Trantenroth finds that in about half the cases of pregnancy in healthy women, primiparæ or otherwise, a trifling amount of albuminuria is to be detected in the second half of pregnancy. (*The British Medical Journal.*) In a minority of cases thiss ymptom is not due to renal changes; in the majority it represents a special morbid condition, best termed "the kidney of pregnancy." As a rule this condition involves no symptoms besides changes in the kidney. Eclampsia and œdema are rare. The pregnancy kidney never changes into the kidney of any chronic form of nephritis. There is no true nephritis of pregnancy. Albuminuria is the rule during labor, especially in primiparæ, and casts (usually hyaline) are to be found in almost a third of the cases. In the albuminuria of pregnancy casts are much rarer. The albuminuria of labor is most marked during the period of dilatation, and disappears rapidly during childbed, except when there is fever. Later on, toward the second week, albuminuria usually indicates catarrh of the lower part of the urinary tract. The albuminuria of pregnancy and labor does not render chloroform dangerous. Renal disease existing before pregnancy is greatly aggravated by that condition, often ending in death of the ovum and abortion, after which the disease abates more or less. The causes of pregnancy kidney are the increase of intra-abdominal pressure, changes in the nutrition of the kidney brought about by the altered condition of the blood, and, in special cases, obstruction of the left ovarian vein which joins the left renal, and compression of the ureter by the fœtal head. The last two causes apply to the kidney of labor (*Geburtsniere*), where also septic changes from pieces of fœtal appendages play a part. The degree of the changes which make up the kidney of pregnancy depends on the resisting power of that organ in the individual patient.

Cramp and Angina Pectoris.—For more than a century following Heberden, angina pectoris has been considered by a large part, if not the majority, of the profession, as caused by a spasm of the cardiac muscle analogous to those often met in the limbs. There have been offered a number of reasons, however, why such a spasm is incomplete to account for all the phenomena of an attack of angina. Dr. F. P. Weber, in a recent communication, speaks of the ordinary angina attack (following Huchard, "Maladies du Cœur," 2d Ed., Paris, 1893) as analogous to the condition described as "claudication intermittente" by Charcot and others. (*American Journal of the Medical Sciences.*)

This latter condition was originally noted in horses, consisting of a sudden loss of power, accompanied with pain, anæsthesia of the limb affected, with sometimes rigidity. Presently this wears off, and the horse proceeds, only to have another and another attack if urged too rapidly. It has been found in these animals, that there has been a closure of some form of the vessels supplying the affected part. A similar condition has been described in man. It is believed that this lack of power is due to insufficiency of the blood-current, and that the pain is also the result of this ischæmia. Occasionally, probably from the insufficiency of the restricted blood-supply to remove useless and irritative waste products, a cramp occurs; and this may be associated with the loss of power, pain, etc. Thus, after or in great exertions the blood-supply is insufficient to keep up the tone of the exercised muscles, and a temporary uselessness occurs. Often rigidity also occurs, but not necessarily. Sometimes the cramps occur without being preceded by any marked diminution of power, etc. So in disease of the vessels resulting in gangrene, pains are sometimes felt from the lack of nutrition to the sensory nerve-endings; or even lack of power may occur, as premonitory of the oncoming gangrene. Thus it is believed that the ordinary angina, in which a loose, flaccid pulse is met, is really an instance of claudication due to the absence of sufficient blood, caused by coronary closure; the cramps which sometimes occur generally leading to a fatal termination, and the heart stopping in systole—the non-fatal attacks being unaccompanied by cramp, and only showing a lowered muscular power of the heart, together with pain.

Clinical Department.

HERNIA—STRANGULATION RELIEVED BY GASEOUS DISTENTION CURED BY PREGNANCY.

By I. L. VAN ZANDT, M.D.,

FORT WORTH, TEX.

Mrs. W——, five days sick with typhoid fever, presented symptoms of occlusion of the bowels. My attention was directed to a tumor, seemingly an abdominal hernia, situated about two to three inches laterally from the umbilicus. I made some efforts to reduce by taxis and to move the bowels, but being impressed with the gravity of strangulated hernia or other mechanical obstruction I did not waste much time with purgatives or other temporizing methods. Procuring a strong rubber-cloth bag, a relic of the sulphuretted hydrogen craze, with the necessary generator, pipes, cut-offs, etc., I, from bicarbonate of soda and an acid, filled the bag, holding probably two gallons, with carbonic acid gas. The bag was then cut off from the generator, and connected with the bowel by a rubber syringe (Davidson's pattern). Finding I could not pump the gas with the syringe, I resorted to pressure on the bag between the bed-railing and my knee. I forced the gas in as fast as the tolerance of the bowel would allow, at times checking temporarily when the patient complained. The abdomen became very tense. About the time the gas was exhausted she began to "belch wind" very freely, the nausea being entirely relieved. In due time the bowels moved, and this was the end of this trouble, though the tumor was not entirely reduced. The fever ran a mild course, the patient getting up inside of four weeks.

Mrs. W——, was at this time about three or four months pregnant. The pregnancy continued to term, when she was delivered of a fine boy. This occurred while she was on a visit in Missouri. On her return I found that the hernial tumor had entirely disappeared, the uterine globe (as I suppose), in its advance causing a traction within that caused a complete withdrawal of the omentum or intestine filling the sac and allowing the orifice to close.

In this connection I would mention that I once saw a congenital umbilical hernia in a pig cured in a somewhat similar way. The pig was about three months old when acorns began to ripen. In a very short time the tumor shrank away and never again appeared. In this case I think the stomach in distending drew on the mesentery so as to pull the contents of the tumor into the abdominal cavity, and then kept the orifice covered till it closed.

A CASE OF MULTIPLE ABSCESSES OF RIGHT LUNG WITHOUT STRICTURE OF THE BRONCHI.

By WILLIAM F. NEUMANN, M.D.,

HOUSE PHYSICIAN TO THE ST. FRANCIS HOSPITAL, NEW YORK.

Herman K——, aged fifty-nine, native of Austria, hat-maker, was admitted to St. Francis Hospital, August 30, 1894. Family history was negative.

Personal history: Gonorrhœa at age of twenty-five; no history of syphilis. No rheumatic or malarial history. No marked alcoholic habit. Patient gave no history of previous lung trouble or injury to the chest.

Patient states that he had always enjoyed good health up to the time of his present illness, which began about six months ago with pain in the chest.

For the past six months patient has had periodical attacks of pain in the chest, more marked on the right side. This pain is very intense, and is described as being sharp and shooting in character, and at times running into the right shoulder and down the arm to the elbow.

There is a slight cough with scanty mucoid expectoration in the morning; no night-sweats, slight loss of flesh and strength. He has been troubled more or less with dyspnœa for many years past, but dyspnœa has increased in severity during the past six months; appetite good, bowels regular.

Patient is somewhat anæmic and emaciated. Inspection of chest shows a marked bulging on right side anteriorly, at third and fourth intercostal spaces close to the right edge of the sternum, very tender on pressure. Skin over swelling is reddened and pits on pressure.

Physical examination: There is marked dulness over the right side anteriorly, extending from the clavicle to the upper margin of the fifth rib. Posteriorly, on the right side, dulness extends from supra-spinous fossa to one-half inch below the angle of the scapula. Respiratory murmur over right chest is somewhat diminished and distant, with prolonged harsh expiratory murmur at apex. Vocal resonance and fremitus also diminished. Breathing over left side of marked emphysematous character. Heart: Apex-beat displaced to the fourth intercostal space and situated about one-half inch from left edge of the sternum. Faint inconstant systolic bruit heard at the apex. Arteries slightly thickened. August 30, 1894, short hypodermic needle introduced in third interspace close to the right edge of the sternum, but no pus was found.

Pain continued to increase in severity and necessitated the use of morphine to secure sleep. Pain in right shoulder and arm now became so severe that the slightest movement caused the patient to cry out. On September 7, 1894, a distinct area of fluctuation could be made out at the third interspace; a long aspirating-needle was introduced and one-half drachm of creamy-yellow, ill-smelling pus was obtained. Patient was immediately transferred to the surgical division. Tumor steadily increased in size, now extending from second to the fifth ribs, and pain was excruciating.

September 13, 1894, operation by Dr. F. Kammerer. Incision was made over the tumor in the third

intercostal space, about two and one-half inches in length, and about one-half pint of creamy-yellow pus evacuated. Drainage-tube was then inserted and the cavity packed with iodoform gauze. A few days later another incision was made in the fourth intercostal space and the two connected by a drainage-tube, the tube lying directly on the ribs.

A few days later an aspirating-needle was introduced posteriorly on the right side, in the eighth intercostal space, and pus found. It was now decided to exsect a portion of one or more ribs, and in this way to thoroughly drain the pleural cavity. Patient was anæsthetized and about one inch of the eighth rib was exsected, but before opening the pleural cavity a needle was introduced, and strange to say, instead of pus, a syringeful of clear straw-colored serum was obtained. As this made the diagnosis doubly doubtful, the operation was abandoned and the pleura left intact, although the rib had been exsected. Openings anteriorly were irrigated daily with Thiersch solution and packed with iodoform gauze. Patient gradually grew worse, and died on October 3, 1894.

October 4, 1894, autopsy by Dr. Hodenpyl, to whom I am indebted for the following notes: Few old adhesions over left lung. Left lung emphysematous and extending about one and a half inch to right of the median line; posterior part of lower lobe of left lung a little congested, otherwise normal. Heart, flabby; a few calcareous areas over the aortic valves. Little old thickening of the mitral valve. Right pleural cavity contains a considerable amount of pus. Lower and middle lobes of right lung converted into a series of abscess cavities with smooth walls, and containing thick pus. In addition to these there are two large cavities in the posterior part of the lower lobe, which contain fibrin and clear straw-colored fluid. Liver shows a little chronic congestion. Kidneys large and congested, one containing a small cyst. Cortex thick, markings fairly good, capsule not adherent. Dissection of the lung shows these cavities to be in communication with the bronchi. Dissection of right bronchus from bifurcation of the trachea shows no stricture. Pus contained no actinomyces or tubercle bacilli.

Diagnosis.—Multiple abscesses of right lung without stricture of the bronchi; empyema.

A CASE OF HICCOUGH.

By RALPH WAIT PARSONS, M.D.,

SING SING, N. Y.

A RATHER remarkable case of singultus came under my observation about two years ago. The patient, a dentist and a native of this State, had had melancholia for twenty years, and a few days before admission to the hospital had developed suicidal impulses. After admission, when the attendant removed the patient's shoes, it was found that the great toe of the right foot had been completely severed from its metatarso-phalangeal articulation. After this operation had been performed, the patient had replaced the severed toe in its normal apposition to the foot, and had concealed the mutilated part with his sock and shoe. He had committed this act of self-mutilation three days previous to being sent to the hospital, but during this time had evinced no signs of lameness, nor given evidence of physical suffering.

A few days after admission the patient developed an attack of singultus, which was repeated several times during the day, each attack lasting ten or fifteen minutes, the hiccough being as frequent as ten or fifteen per minute. After a time the attacks became more frequent and more prolonged, and the hiccoughs became as frequent as forty per minute. Every remedy was tried that could be thought of to relieve this distressing condition, but to no avail. Nitrite of amyl and nitroglycerine were, at first, of temporary value in controlling the attacks, but later failed to be of any service. The patient could not retain any food in the stomach, and although nutrient and stimulating enemata were administered at frequent intervals, he became rapidly exhausted and died in about thirty-six hours after the onset of the first attack of singultus.

Whether there was any connection between the surgical injury previously sustained and the attacks of singultus is, of course, difficult to decide.

A LARGE DOSE OF TINCTURE OF ARNICA.

By JOHN A. McKINNON, M.D.,

SELMA, ALA.

MR. J. W——, who has been on a debauch for the past three months, had an attack of delirium tremens, with persistent insomnia, for which he took elixir peraldehyde, which was put up in a four-ounce bottle. He had the conventional black eye, which he was very solicitous to have removed. To satisfy him the following prescription was written:

℞. Tinct. arnicæ ..... fl ℥ ijss.
Ext. hamamelis ..... fl ℥ iss.
M. Sig.: For external use only.

Having passed a restless night, at 4 A.M. he arose, poured out the liniment into a glass, filled the glass with water and drank it all down at one time. It was 6 A.M. before he discovered his mistake, when, becoming alarmed, he sent for me. There was nothing that could be observed about him showing any poisonous effect of the drugs, except slight exhilaration, which might be attributable to the alcohol he had taken in the liniment. His kidneys acted quite freely twelve hours after taking the drug, otherwise there has never been any other perceptible effect from it.

CASTRATION FOR HYPERTROPHY OF THE PROSTATE.

By A. T. PIERCY, M.D.,

PLACERVILLE, CAL.

PERMIT me to report the following: O. B——, aged seventy-one, came under my care late in July, 1894. His complaint was occasional retention of urine, the periods of retention becoming much more frequent of late. On attempting to pass a catheter I found the prostate immensely enlarged, and, from his efforts at urination, crowded down against the perineum and wedged between the rectum and pubic arch. So tightly was it pressed against the pubic bone that it was next to impossible to introduce a catheter. I succeeded in relieving him with a catheter, but the retention recurring in a few days, I proposed castration.

The operation was readily accepted, and on August 8th last I removed both testes. The day following he passed his urine much more readily than he had in some weeks before. The wounds healed without suppuration, I permitting him to sit in a chair and walk about his room on the third day after operation. After two weeks he had no further trouble passing urine, and on examination, October 8th, two months after castration, I found the prostate diminished at least one-half. I may add that he is highly pleased with the result of the operation.

Certainly there is a brighter prospect for the relief of aged sufferers from enlarged prostates.

New Medical Baronets.—Dr. J. Russell Reynolds and Mr. John Erichsen have been made medical baronets.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, February 23, 1895.

INSOLVENT HOSPITALS.

THE London hospitals are actually going into a condition of insolvency, or at least are closing many of their wards for want of funds.

In regard to some of these institutions the note of impecuniosity, says *The Lancet*, is pitiful. In St. Thomas's Hospital three wards are standing empty, and two others are temporarily devoted to the reception of paying patients. In the Metropolitan Hospital accounts are "overdue," and funds needed for their payment. At the Margate Infirmary 130 beds out of 220 beds are closed for want of funds. At the Middlesex Hospital last year the income from all sources (legacies included) amounted to £20,357, and the expenditure (due to repairs, etc.) to £37,184.

Thirteen of London's large hospitals are suffering from want of funds. Whole wards are closed in some of the oldest, greatest, and best hospitals. In one of the youngest a considerable proportion of the beds has been set apart for pay patients, to the exclusion, of course, of those who cannot pay and for whom this and all other hospitals were primarily built.

Now, philanthropy is not on the whole declining. There never was a time when more money or more unselfish efforts were bestowed upon the unfortunate.

Perhaps, therefore, instead of bemoaning human selfishness the managers of hospitals had better consider whether they have not made some mistakes in their work. Have they not attempted to overdo their charities? And have they been quite just to medical men upon whose services they depend, but for whose services they tender slight acknowledgment. The great hospitals of London have, it is said, been sources of abuse of medical charity and perhaps have alienated somewhat the cordial support of the medical fraternity as a whole. A similar condition of things presumably awaits us here.

DOCTORS AND FREEMASONRY.

MR. R. T. GOULD, an eminent Mason and recognized authority on masonic history, has written an elaborate article in which he, though a layman, generously tries to prove that the medical profession has distinguished itself more than any other in the service of Symbolical Masonry. He says: "I must show you, if I can, that it is by the influence of brethren who have been, or are, practitioners in medicine or surgery, more than to the members of any other single profession, that Freemasonry has been shaped and moulded into the form—or perhaps it would be best to say the system (or set of systems)—in which we now possess it."

Mr. Gould gives a long list of the prominent English physicians who were high in the masonic mysteries. Among these were Edward Jenner, Sir Erasmus Wilson, Sir William Ferguson, and Sir James Simpson. We doubt if Masonry has taken so marked a hold upon the profession of this country. Mr. Gould refers to one American, Dr. Winslow Lewis, of whom Dr. Holmes wrote:

> "You hear that man laugh? You think he's all fun,
> But the angels laugh too at the good he has done;
> The children laugh loud as they troop at his call,
> And the poor man that knows him laughs loudest of all."

SCIENTIFIC VERSUS OBSCENE MEDICAL LITERATURE.

IN the laudable aim of reforming existing abuses, it is often difficult to draw the line in such a way that none but the guilty shall be punished. Whenever any doubt obtains as to the precise intent of a proceeding having such an end in view, it sometimes happens the said doubt is on the wrong side.

This may prove to be the case in regard to the sweeping resolution offered by Dr. Jacobi, at a recent meeting of the New York Academy of Medicine, having for its ostensible purpose the endorsement of a bill to compel the payment of letter postage and the use of sealed envelopes for the transmission of medical pamphlets and circulars the contents of which are not appropriate for general or public reading. To anyone who will casually read the proposition, the course advocated would appear to be eminently proper.

There is no doubt that the distinguished gentleman refers to the obscene pamphlets which often, under the guise of scientific literature, are industriously circulated by quacks, and find their way so cheaply and frequently through the mails to the homes of innocent and unsuspecting people. So far, it does credit to the heart and head of one who is generally foremost in such matters of radical reform as tend to benefit society, and elevate the standard of the profession.

It appears to us, however, very difficult to understand how the difference can be made apparent, to post-office officials, for instance, between what is a strictly scientific pamphlet, periodical or circular, and the advertisement of an unprincipled, designing, and obscene quack. Obscenity, strictly speaking, is only a relative term which takes force from the motive or purpose actuating its commission. Thus, while from a properly scientific standpoint, with the sole intent of obtaining useful knowledge, it would be impossible to offend chastity or foul a pure mind, the contrary would be the case with the same phrases and the same illustrations used in an unchaste and suggestive way. But who shall be able to distinguish between the real and pseudo-scientific publications in which the phrases or illustrations may occur? It strikes us that this is a question of quite serious import to the great number of scientific journals that from time to time publish

what a layman would consider indecent representations of the human form divine. Even the most deaconish scientist must sometimes look bashfully askance when some of the startling living pictures of the gynecological zone are displayed between the chaste sheets of many of our most respectable contemporaries.

Such illustrations are oftentimes absolutely necessary for the proper understanding of the subject under discussion, and yet they are by no means suitable for general distribution at an afternoon tea, or public discussion at a church sociable. Even the MEDICAL RECORD, which has the enviable reputation with the public of being always decent, may not always display some of her pages in crowded street-cars, nor vaunt herself unseemingly on the drawing-room table of a family with growing children.

To the truly scientific man or woman, however, everything is pure. In fact, there can be no such thing as obscenity when true science investigates. But if, strictly speaking, the new law virtually defines obscene literature as that which is not fit for general inspection or public reading, every medical journal in the State would be dodging through the mails in sealed envelopes and be ruinously weighted with letter postage. Indeed, it would be impossible to publish and circulate scientific journals with such rates.

It strikes us, therefore, that requisite care should be taken to prevent the latter possibilities, and in our efforts to reform existing abuses, we should be on the lookout not to create new or unlooked-for possibilities of injury in other directions. It might be possible, perhaps, to make distinction in favor of regular scientific periodicals, but here again, what form of law can be competent to such an end? Sometimes, in attempting to kill the bear we may shoot our own dog.

CAUTION IN THE USE OF ANIMAL EXTRACTS.

IN a previous issue, reference was made to beneficial results having been noted, in a case where the injection of a preparation of the supra-renal capsule was used for curative purposes. We therefore consider it our duty to draw the attention of our readers to recent researches, made in England by Dr. Oliver, of Harrogate, which point to a great danger attending the use of such remedies.

We are indebted to Dr. Addison, of Guy's Hospital, London, for the first hints regarding the connection between certain diseases which always proved fatal and certain conditions discovered in the supra-renal capsule after death; but it was Brown-Séquard who first demonstrated that the total removal of these bodies had a fatal result, accompanied by an alteration in the blood which rendered that fluid poisonous to other animals.

More recently Dr. Oliver has discovered that, in both alcoholic and watery extracts of the supra-renal capsule, a most potent substance is produced.

If only as much as a grain by weight of this organ be extruded with alcohol and allowed to dry, and then be redissolved in a little water or salt solution, the most extraordinary results will follow if this fluid is injected into the blood of a dog.

It will raise the pressure of the blood within the arterial system to an enormous extent, so that, from a blood-pressure which would be sufficient to balance a column of some four inches of mercury, the pressure may rise so high as to be equal to a column of mercury of twelve or more inches. Such result being obtained by a very minute dose. As Dr. Oliver states, we have here to do with a substance as potent, although in a different direction, as strychnia.

These facts we make known in the hope that they may serve as a caution to those making use of the organs of animals in their practice, as they clearly point to the conclusion that the whole subject must be investigated further, before such remedies can be administered without the greatest caution.

News of the Week.

Cholera in Constantinople.—The cholera reports from Europe are beginning early this year. On February 8th a cablegram reported eleven cases of the disease in Constantinople, seven of which were among the Turkish troops. During the week following, there were sixty-one cases and twenty-nine deaths.

Execution by Electricity.—A bill for the execution of death sentences by electricity has been introduced in the West Virginia Legislature.

Helmholtz's Birthplace.—A tablet has been placed over the door of 8 Hoditz Street, in Potsdam, where Helmholtz was born.

Dr. F. W. Ring, assistant surgeon to the Manhattan Eye and Ear Hospital of New York, has been appointed Ophthalmic Surgeon to the Connecticut State Hospital, in New Haven.

The Late Dr. Alfred L. Loomis.—At the meeting of the New York Pathological Society, held February 13, 1895, the following resolutions on the death of Dr. Alfred L. Loomis were adopted and spread on the minutes, and the secretary requested to send a copy of the same to the New York MEDICAL RECORD and the New York *Medical Journal* for publication:

Whereas, It becomes our duty to announce the death of Dr. Alfred L. Loomis, a former President, and for a long period a cherished member, of the New York Pathological Society; therefore be it

Resolved, That this Society desires to place on record its high estimation of those qualities for faithful, persistent, and skilful work which characterized all his efforts during more than a quarter of a century of active membership.

Resolved, That his minute and painstaking study of clinical facts in connection with pathological lesions, and his logical demonstrations of their practical significance, constantly proved his eminent fitness as a safe teacher, and his high and rare qualifications as a leading authority.

Resolved, That his example of indefatigable labor in this Society, his ever-ready willingness to advance its best interests by valuable contributions from his large

experience, and his earnestness of purpose in extending its usefulness, are grateful remembrances of his unselfish ardor, of his conscientious regard of duty, and of his earnest devotion to the highest aims of pathological research.

George F. Shrady, M.D.
Edward G. Janeway, M.D.
John H. Hinton, M.D.

Death of an Eminent German Professor.—Dr. Edward Külz, Professor of Physiology at the University of Marburg, died recently at the age of fifty years. His name is best known in connection with diabetes mellitus, of which disease he was a student nearly his entire life. He was not very popular with the students at the University, as he was known as a very severe examiner; at one time, indeed, there was an open rebellion, and the students refused to attend his lectures, the intervention of the Minister of Public Instruction being required to bring about a truce. It is generally believed that Dr. Külz was for a long time the private adviser of the German Government in matters relating to medical education.

Criticising a Health Officer.—Fifty physicians of Detroit met recently and adopted resolutions severely criticising the Health Officer for having, as alleged, reported as chicken-pox cases of small-pox which had been diagnosed by competent physicians.

A Correction.—Dr. W. F. Mittendorf writes: "In the report on my paper on 'Blennorrhœa of the New-born,' read at the State Medical Society at Albany, a misprint occurred. It is not borax, but one part of boric acid to nine parts of vaseline, which I have recommended to be used in this affection. As the object of my paper was to place into the hands of the general practitioner a simple remedy which, in case the child cannot be seen or treated by a specialist, can be relied upon and yet do no harm, even if it has to be used as often as every five or ten minutes, night and day, you will do me a great favor by allowing me this explanation and correction."

Four Years' Medical Course at Yale.—The faculty of the medical department of Yale University has decided to extend the course in medicine from three to four years, and a committee consisting of Professor Smith, Dean, and Professors Carmalt and Ferris, has been appointed to perfect plans for the new course, which is to be announced during the next commencement. Good for Yale.

Important Decision in Small-pox Cases.—The General Term of the Supreme Court in Brooklyn has reversed the decision of Justice W. J. Gaynor, in the case of two small-pox patients who were isolated by the Health authorities, and discharged by Justice Gaynor on a writ of habeas corpus. This is part of the opinion of the General Term:

"These relators fell under the control of the Board of Health. They came to the city from infected places, and they were liable to communicate contagion. They were, therefore, proper subjects for isolation, and they were quarantined and detained in their premises. That isolation and detention was clearly within the scope and powers and duties of the Board, and that is all it did. The Board did not require the relators to be vaccinated, and that seems to be the error into which the relators have fallen. They seem to assume that the Board of Health intended to compel them to be vaccinated, but the acts of the Board admit of no such construction. There was neither coercion nor compulsion. The prevention of small-pox is of such paramount importance as to justify all reasonable means for its accomplishment.

"The propriety and wisdom of the course pursued by the Board is beyond criticism. Its acts have all been within the lines of statutory authority, and they have been discreet and in evident good faith, in the presence of an impending pestilential danger."

Collective Investigation upon the Serum Treatment of Diphtheria.—The editors of the *Deutsche Medicinische Wochenschrift*, Drs. Eulenberg and Schwalbe, have initiated a plan for the collective investigation of the experiences of the medical profession regarding the treatment of diphtheria by antitoxin. They point out that the results so far published from private practitioners, as well as those from hospitals, speak favorably of a method which may prove to be of the highest importance in therapeutics—a method which has impressed even the most critical, as exemplified in Professor Virchow's declaration that it is the duty of every practitioner to employ it in this disease. They say that scepticism is never more legitimate than in respect to the alleged efficacy of treatment, especially of any treatment that claims to be specific, and that diphtheria affords scope for arriving at a correct judgment upon the results of treatment; but the number of points to be determined are exceptionally numerous and involve many considerations such as can only be gathered on a large scale and over a large area. The question must embrace facts from thousands of cases collected from all sources and from all parts of the country: hence the idea to undertake a collective investigation throughout Germany similar to that pursued in influenza by the Berlin Society of Internal Medicine, on the lines originated by the British Medical Association. In this scheme they have the support of Drs. Leyden, Litten, Renvers, Heubner, Behring, Ehrlich, and Guttstadt. The cards to be filled up by practitioners can be obtained from the office of the journal. It is proposed to close the inquiry on April 1, 1895.

Theatrical Play-bills and Medical Practice.—What is the use of a law in the State of New York regulating the practice of medicine, when the theatres are allowed to publish remedies for dangerous affections. In other words, when the conductors of the advertising sheets, on which the play-bill is placed, are permitted to practise medicine without license. What we mean by this may be illustrated by the fact that one of these papers recently gave an elaborate prescription for treatment of inflammation of the eyes. This prescription was the far-famed poultice of tea-leaves, which has, to the experience of many ophthalmic surgeons, destroyed thousands of eyes. Everybody is ready to practise medicine, and in self-limited affections we may, perhaps, smile at newspaper recipes, so long as they are not dangerous, but in the present imperfect mental condition of the public, in our country at least, it is not safe to

allow advertising journals to prescribe dangerous remedies for so valuable a part of the human organism as the eyes.—*The Post-Graduate.*

Fifty Years in Practice.—A complimentary dinner was given on the night of February 12th, by the Syracuse Academy of Medicine, to Dr. Joseph P. Dunlap, of that city, in commemoration of his fiftieth year of active practice. The members were in full attendance, together with representative citizens. Appropriate addresses, dwelling on the life and character of the honored guest, were made by Drs. Mercer, Van der Warker, Bannan, Dallas, Didima, Hon. Frank Hiscock, Hon. J. J. Belden, Rev. L. M. Clarke, and Dr. Van Duyn. We are pleased to hear that Dr. Dunlap is still up to his work and in the enjoyment of good health. We extend to him on behalf of his distant friends a hearty greeting.

The Twelfth International Medical Congress.—Preparations are already in active progress in Moscow for the twelfth International Medical Congress, which is to take place in that city in 1897. The Organizing Committee includes all the professors in the Medical Faculty of the University of Moscow, under the presidency of the Curator of the Moscow Teaching Staff, Count Kapnist. A special Executive Committee, under the presidency of Dr. Klein, Professor of Morbid Anatomy, and Dean of the Medical Faculty, has been intrusted with the preliminary arrangements for the Congress.

Northwestern Ohio Medical Association.—The forty-ninth semi-annual meeting of the Northwestern Ohio Medical Association closed its session at Lima, O., December 19, 1894. The following officers were elected: *President*, Dr. J. K. Woods, Lima; *Vice-President*, Dr. Joseph Sager, Celina; *Second Vice-President*, Dr. W. E. Hoover, Lima; *Secretary*, Dr. Charles Graefer, Sandusky. The next meeting will be held at Findlay, June, 1895.

The Academy of Stomatology, of Philadelphia, a new association of dental practitioners, has been organized for the purpose of investigating and studying all matters connected with the mouth, its functions in health, and their aberrations in disease. The academy, we learn, already numbers among its members a majority of the most active and advanced dentists of Philadelphia, men who have the best interests of dentistry at heart, and who energetically forward the work of dental professional progress to the best of their ability and means. The academy has secured a handsome suite of rooms for its exclusive use in the holding of its meetings, clinics, etc. In connection with these a dental library and museum is being established, together with a reading-room, where it is proposed to keep on file all the leading dental periodicals of the world. The reading-room and museum will be open to members at all times during the day and evening, and it is expected that the facilities thus offered for consulting the periodical literature of dentistry will be largely patronized by the profession of Philadelphia and vicinity. The ultimate purpose of the academy is to establish a library and museum related to stomatology which will be consulted by dental practitioners throughout the entire country.

Reviews and Notices.

Medical Jurisprudence, Forensic Medicine, and Toxicology. By R. A. Witthaus, A.M., M.D., Professor of Chemistry, Physics, and Hygiene in the University of the City of New York, etc., and Tracy C. Becker, A. B., LL.B., Counsellor-at-Law, Professor of Criminal Law and Medical Jurisprudence in the University of Buffalo. With the collaboration of August Becker, Esq.; Charles A. Boston, Esq.; W. N. Bullard, M.D.; J. Clifton Edgar, M.D.; D. S. Lamb, M.D.; W. B. Outten, M.D.; Hon. William A. Poste; Edward S. Wood, M.D.; E. V. Stoddard, M.D.; Hon. Goodwin Brown; J. C. Cameron, M.D.; E. D. Fisher, M.D.; H. P. Loomis, M.D.; Roswell Park, M.D.; Irving C. Rosse, M.D.; F. P. Vandenbergh, M.D.; J. H. Woodward, M.D.; George Woolsey, M.D. Vols. I. and II. New York: William Wood & Company. 1894.

The first volume of this important publication is devoted to medical jurisprudence and forensic medicine. The legal relations of physicians and surgeons are ably set forth in an elaborate essay by Mr. Becker. This article is well worth reading, as it deals with matters often neglected by physicians to their own great detriment. The right to compensation and the legal methods of enforcing this right may be studied with equal advantage by beginners and those well advanced in practice.

The powers and duties of coroners are clearly defined in an article by Mr. A. Becker. Dr. H. P. Loomis writes on medico-legal autopsies in a concisely worded contribution. The various modes of death, personal identity, the determination of the time of death, and medico-legal considerations of wounds, are all ably handled by expert writers, whose words carry with them the weight of authority.

Altogether it appears from a careful examination of this volume that the different contributors have succeeded in placing before the profession a collection of essays that cover the entire ground of forensic medicine in an eminently satisfactory manner. The mechanical execution of the book is in keeping with the high character of its contents.

The second volume of this work is also peculiarly valuable in a practical way from many points of view, considering the variety and importance of the subjects discussed. The opening chapters, on the examination of blood and other stains, and of hair, are by Professor Wood, of Harvard, whose work, as every medical man knows, is always accurate and scholarly.

Dr. Cameron, of Montreal, contributes a valuable chapter on abortion and infanticide.

Dr. Edgar's article on pregnancy, labor, and the puerperal state, is excellent, showing evidence of thorough research and practical experience. Each section is supplemented by a list of illustrative cases. The fascinating subject of post-mortem parturition is presented in a most interesting way. The same writer is a joint author with Dr. Johnston of the admirable article on rape.

Dr. Outten's valuable monograph on railway injuries, consisting of four chapters and including one hundred and eighty pages, will be consulted with profit by all who desire thorough information on this important subject. A carefully prepared index and tables of cases cited in the text are appended.

Identification of Criminals. — England has just adopted the Bertillon system of minute anthropometric measurements for the identification of criminals, in addition to Herschell's finger-print system, which Mr. Francis Galton has made generally known.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, December 7, 1894.

H. F. Walker, M.D., President, in the Chair.

Note on the Causes and Premonitions of Apoplexy, from Analysis of One Hundred and Eighty Cases.—Dr. C. L. Dana read the paper (see p. 225).

Dr. Abbe had been interested in the statement that often just before an apoplectic attack patients felt in the best possible condition. He recalled two cases of fatal apoplexy in old people, whose families had remarked upon their bright, active condition the day of the stroke.

Dr. H. M. Biggs had understood the author to say that in his opinion most syphilitic cases of apoplexy were due to cerebral softening. In his own experience with these cases there had been complete recovery, and he had not been satisfied as to what was the cause of the hemiplegia. If it was due to softening, it did not seem that there could be complete recovery. During the past year he had seen a number of cases of that type; in several of them the hemiplegia persisted three or four months, was accompanied at first by coma, then a stuporous condition, but eventually there had been complete recovery. He repeated, that if the cause were softening, one would not expect complete recovery.

Dr. J. D. Bryant inquired whether the percentages given related only to the total number of deaths, or to the number of living. If to the latter, inferences based upon the statistics would be more reliable.

Dr. Dana, in reply, repeated some of the facts contained in the paper.

Dr. Bryant mentioned a case recently seen, of an elderly lady who awoke one morning, complaining that she could not swallow and of a slight sensation of strangulation. Examination twenty-four hours afterward showed partial hemiplegia or paresis of the entire side. She had since recovered to a considerable degree, and at present was able to use the hand freely. There was no history of thrombus, embolus, or dreams the night of the stroke.

Tobacco and Apoplexy.—Dr. W. M. Polk wished to know more about the case in which tobacco had seemed to cause the apoplexy. Was it by direct effect of the nicotine, or by inducing, for instance, the uric-acid diathesis? His own impression had been that persons who, on account of faulty assimilation, formed a good deal of uric acid, were more prone to apoplexy than others. There were a good many people in whom the use of tobacco favored such faulty assimilation.

Dr. Dana replied that personally he did not think tobacco predisposed to apoplexy in any way. One reason for this belief was the fact that apoplexy of various kinds occurred nearly as frequently in women as in men, and the slight difference might be explained by the greater frequency of syphilis and alcoholism in men. Tobacco tended to lower the arterial tone and perhaps to prevent rather than favor arterial sclerosis and apoplexy. He had quoted the two cases in his paper only because the patients themselves had laid stress on their excessive indulgence in tobacco while other causes were not apparent.

Dr. Robinson inquired of the author whether in the cases of syphilis the initial lesion had, as a rule, been followed by other syphilitic manifestations? Was apoplexy more likely to occur in syphilitics with further manifestations of the disease than the initial sore alone?

Dr. Dana replied that the cases in which he had attributed the trouble to syphilis there was a distinct history of syphilitis infection, followed by subsequent manifestations of the disease, including the prodromal symptoms of syphilitic hemiplegia. In looking over his records he had been rather surprised to find how frequently syphilis was the cause.

Dr. Andrew H. Smith asked on what basis Dr. Dana had distinguished between cases of hemorrhage and of embolism, except that of cardiac disease and vascular sclerosis.

Dr. Dana replied that in eighty cases the diagnosis was based on autopsy. These showed that in syphilitic cases the condition was so uniformly one of blocking of the arteries and softening that it could be safely inferred the same condition existed in the living patients presenting hemiplegia with a distinct syphilitic history, including headache, etc. He asked Dr. Delafield if his experience had been similar.

A Question of Arterial Degeneration.—Dr. Delafield thought differences of opinion were apt to depend upon different ways of taking up the subject. Dr. Dana had taken up the subject from the point of view of apoplexy; but, after all, the real study was that of inflammation of arteries. What the author apparently meant by apoplexy was that the person was hemiplegic, and if a person was hemiplegic it meant either that a diseased artery had ruptured, or had become obstructed, or in some way interfered with the circulation for a longer or shorter time. It had always seemed to him that the weak point in the study of apoplexy was as a cerebral lesion, while the real study should be that of inflammation of arteries.

Dr. Dana remarked that Dr. Delafield spoke from the stand-point of the pathologist, while his own experience had been as a teacher. In order to make students understand the question it seemed necessary to speak clinically. Practising physicians followed one better and understood him better when he spoke from that stand-point.

Dr. Delafield thought that was simply keeping them in the paths of ignorance.

Dr. Dana remarked that to take up the subject of arterial inflammation would require one to go over about a third of the entire field of medicine.

Dr. A. H. Smith asked how about cases in which an embolus was carried into a healthy artery.

Dr. Delafield said of course that occurs, but it is seldom.

The President mentioned a case of hemiplegia coming on, some years ago, three days after confinement. Before confinement the urine had been normal, but at the time of confinement it contained albumin and casts, which disappeared afterward.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, December 27, 1894.

Malcolm McLean, M.D., Chairman.

Hysterectomy after Removal of Uterine Adnexa.—Dr. H. C. Coe, in presenting a specimen, said he had once taken ground with many others against those who had advocated removal of the uterus in nearly all cases where it was necessary to take out the adnexa. Lately, however, he was rapidly becoming converted to the view of the other side. The uterus shown was from a patient who some months before had had both ovaries removed. Relief was not obtained, and lately she had been bleeding profusely. The uterus was felt to be large and heavy, and a tumor was present at one side. He removed the uterus and tumor through the vagina according to the new method. The tumor proved to be a cyst of the left broad ligament the size of an orange.

This was only one of a number of cases in which patients had to come to him with a similar condition fol-

lowing successful removal of the uterine adnexa, and while he had once wondered why they should have such persistent pains and other nervous symptoms, he was now coming to the opinion that it was because of allowing the uterus to remain.

Dr. Vineberg related a similar experience, the case of a woman in whom the appendages had been removed at two operations, but pain and hemorrhage continued, compelling him to do hysterectomy. The uterus was large and heavy, in a condition of fibrosis or areolar hyperplasia, and a small mass existed at one side. He thought it was another case in which it would have been better to remove uterus as well as adnexa in the first instance.

Dr. Jarman, who had first seen Dr. Coe's patient at the clinic from whence she was referred to him for operation, made some remarks upon the extreme hemorrhage and difficulty of controlling it. Greatest benefit had come from placing an ice-bag over the spine in the lumbar region, as had also been true of some other cases of uterine hemorrhage.

Dr. Coe said this was the fourth case in which he had found cyst of the broad ligament follow removal of the tubes and ovaries, and he thought it was due in some way to ligation of the vessels.

Ectopic Pregnancy.—Dr. Vineberg presented what appeared like a uterine mole, but which was the tumor of tubal pregnancy removed some weeks after the first symptoms of rupture. Old and fresh blood-clots were found; doubtless marking recurring pains and fainting spells, although the severity of these had not, the speaker thought, depended so much upon the amount of hemorrhage as upon the shock. For comparison Dr. Vineberg also presented a fleshy mole of the uterus from a woman who had had uterine hemorrhages for two or three months, then had gone an equal length of time without, then expelled the tumor which contained a small fœtus.

Free Hemorrhage and Hemorrhage into a Præformed Cavity.—Dr. Coe thought there was a difference in the virulence of the symptoms in cases of ruptured ectopic pregnancy according to whether the hemorrhage was free or whether it took place into a præformed cavity. Where the hemorrhage was into a cavity which had previously been formed by adhesions the symptoms were less severe. The extremely serious nature of the other class of cases, those in which hemorrhage was free into the broad ligament or peritoneal cavity, was shown by a case operated upon by him that afternoon. The woman had been quite well, and was struck down in the theatre as suddenly as if shot. He operated some four hours afterward and found hemorrhage continuing. Decidual membrane was removed, but the fœtus was not found.

The Chairman inquired whether any of the members had met with a case of rupture of tubal pregnancy in which there had not been irregular menstrual flow. Personally he regarded absence of history of irregular uterine flow as evidence that the case was not one of ectopic pregnancy, although, like in a case of his own, there might be a tumor and other signs pointing that way.

Dr. Collyer related a case of tubal pregnancy with rupture in which the uterine end of the tube was not at all distended, showing that it would have been impossible for it to have become a uterine pregnancy.

Uterine Irrigation Tube.—Dr. E. A. Tucker showed a tube which he had devised for use in irrigating the uterus and vagina. It had been constructed especially to secure return flow, a requisite which he had found was not satisfactorily met by other single or double irrigators. It consisted of two glass tubes united so as to form but one at each end. The uterine extremity had side perforations, but no opening at the end, so that the injection could not be forced into the Fallopian tubes. The fluid returned outside the tube along the space between the double portion, which could not be occluded by contraction of the cervix.

Studies in Pelves, Pelvimeters, and Pelvimetry.—Dr. Philander A. Harris, of Paterson, read the paper. There was a small percentage of women, one or two in a thousand, who had a pelvis so small, flattened, or otherwise distorted as to make it impossible for a child of average size to be born alive in the natural way. In addition to this small group there was a much larger one, represented by one woman in fifty or a hundred, whose pelvis was sufficiently contracted in some way or other to embarrass parturition or even endanger the life of mother and child. Almost all pelves which presented osseous impediment could be discovered by external pelvimetry. Inability to find a pelvimeter which might be easily carried about had led Dr. Harris to devise one which combined the qualities of spanning, compactness, and lightness. In order to compare it with others he showed the contour line of the pelvis of a stout woman, life-size, on card-boards, and outlined the various pelvimeters of his collection on the card-boards, the points of the instrument being placed where required to take the external conjugate. The reader showed that the pelvimeters of Byford, Baudelocque, Davis, Collyer, and his own had ample spanning capacity. The latter two occupied about the same space, could easily be carried in the pocket, and could be purchased much cheaper than other instruments.

The author also demonstrated a chart marked "Pelves of normal conformation," designed as a reference table to show, first, the relations which the following measurements bore to one another in pelves of varying size and of normal anatomical conformation; and, further, the relations which such measurements bore to the internal conjugate and to the transverse diameter at the brim. 1. The greatest distance between the iliac crests at their external margins. 2. The distance between the external margins of the anterior-superior spinous processes. 3. The so-called external conjugate.

With these three measurements given, the reader maintained that an appreciation of the relative internal measurements of normal pelves of varying sizes could be had. For instance, an inter-crest measurement of 24 ctm. in a pelvis of normal conformation should have an inter-iliac spinous measurement of 22.2 ctm., and an external conjugate of about 16.5 ctm. Such a pelvis should have an internal conjugate of about 9.5 ctm., and a transverse diameter at brim of 11.1 ctm. Deductions were made for obesity.

Where there was marked deviation from the chart of external measurements we could look for more or less internal asymmetry. Moderate deviation was common, and when put to the test of larger children would cause some difficulty in parturition. The reader held that all who practised obstetrics should regularly measure the pelvis, and for the purpose of study should record their results. The same statement applied to all difficult labors, especially prolonged second stage, in which note should be made of measurements of pelvis and head. Examples were also given of disproportion between height of individual and pelvic measurements.

Illustrative cases of the value of pelvimetry were given, in one case referred to in the paper, with a conjugate of 6.2 ctm. There had been delivery of four small living and three dead children prior to the woman's death in the last accouchement, when a very much larger child was mutilated to effect delivery. Dr. Harris had had experience which taught him that in lesser degrees of contraction test of the capabilities of the patient to deliver herself was not only to be advised, but insisted upon before deciding upon symphyseotomy, or Cæsarean section. Be prepared, however, for operative interference. For more extreme degrees of contraction, *i.e.*, conjugate vera of 6 ctm. or less, purely elective Cæsarean section was to be chosen.

The discussion was participated in by Drs. Marx, Collyer, Tucker, and the author. The former speakers

expressed their appreciation of the great labor expended by the author in preparing his charts, and of the value of pelvimetry in obstetrics. They thought it should be universally practised.

Stated Meeting, January 24, 1895.

MALCOLM MCLEAN, M.D., CHAIRMAN.

Further Report on a Case of Symphyseotomy.—DR. H. J. GARRIGUES presented a woman on whom he had performed symphyseotomy, followed some months afterward by removal of the uterus and appendages. (See p. 234.)

Uterus Removed without Clamp or Ligature.—Dr. Garrigues presented the uterus removed without clamp or ligature in the case of a widow of twenty-eight, who a few months before had parted with tubes and ovaries five or six times their normal size and full of small cysts. Pain remaining the same after the first operation, about three months afterward vaginal hysterectomy was performed. The uterus had become much atrophied meanwhile. The posterior vaginal incision was made, the chain-saw was abandoned for scissors, the vessels were cut with the loss of scarcely a drop of blood. Dr. Garrigues suggested as an explanation of this fact the great thickness of the walls of the branches of the uterine artery, since the lumen of the arteries could be seen constricted and surrounded by a thick ring. Another point of interest was the great extent to which the peritoneum could be pulled off of the muscular coat of the uterus. Fully two-thirds of the organ were thus denuded, and the rest of the peritoneum could be readily dissected off. The entire operation was under the eye, and should a vessel bleed it could readily be seized alone and tied without embracing surrounding tissue in the ligature. The real bleeding, however, was venous, and came from the raw surface between the mucous membrane of the vagina and peritoneum behind the uterus, and could be prevented by uniting the edges with catgut.

Finally, Dr. Garrigues wished to call attention to the advantages of exploratory incision through the vagina. It had none of the disadvantages of abdominal exploratory incision. The new method of removal without clamp or ligature was sometimes referred to as enucleation, but he thought it was not the proper term.

DR. H. N. VINEBERG said that some months ago he presented to the New York Obstetrical Society some cases in which he had removed tubes and ovaries through a vaginal incision, performing what he termed "vaginal cœliotomy." When he began doing vaginal fixation, eighteen months ago, he was struck with the ease with which he could deliver the adnexa through the vaginal incision, if he so desired. But he had not put the method into practice until last autumn. He had recently removed both tubes and ovaries through the vaginal incision in a patient who was able to leave the hospital fourteen days afterward. He made a longitudinal incision in the median line of the anterior vaginal wall, and claimed that this method had the following advantages over the incision in the posterior wall: 1, It was attended with less hemorrhage, and what did occur was under better control; 2, there was no danger of injuring the rectum; 3, in separating the bladder from the uterus and pushing it well out of the way, there was no danger of including the arteries in any ligatures that might be applied; 4, in cases of retroversion and retroflexion the same incision served the purpose of correcting the displacement by doing a vaginal fixation. He was pleased to see that Dr. Garrigues was taking kindly to "vaginal cœliotomy."

Regarding the second case, of removal of uterus without ligature, he would like to sound a note of warning that such a procedure was not free from the danger of subsequent hemorrhage. The cases in which the method was applicable had to be selected. In the case of a small and atrophied uterus, like the one shown by Dr. Garrigues, it was safe enough. But not so in cases of large vascular uteri with extensive adhesions. Instead of saying "no ligatures," he would say the use of ligatures as required to arrest hemorrhage, and not *en masse* to include vessels before they were cut.

DR. JARMAN asked Dr. Garrigues what was the cause of the waddling gait.

DR. GARRIGUES replied that it was the pain, and that both disappeared with removal of the diseased pelvic organs.

DR. JARMAN could hardly understand how pain could cause the waddling gait in this case and in another of symphyseotomy which he had seen. All had seen cases of intense pelvic pain without waddling gait. In the second case to which he referred, the waddling gait was still present at the tenth week, but disappeared after treatment of an abscess and removal of a ligature which had caused the abscess at the site of operation. When the abscess was opened two fingers could be placed between the ends of the pubic bones. He was disposed to think the waddling was cured by contraction of false ligamentous tissue between these bones, holding them rigidly together.

DR. R. A. MURRAY had had a case of symphyseotomy in which the symphysis separated very far, causing doubt whether there would ever be union again; but it took place, and there was no waddling gait. In four cases examined by him carefully after symphyseotomy, he felt underneath the pubic arch bony separation the breadth of his finger, whereas normally it was not more than about an eighth of an inch; yet there was no waddling.

DR. EDGAR mentioned a case of labor to which he was called in a woman who had on a former occasion been subjected to symphyseotomy, but since the pelvis was pretty large he delivered her of a seven-pound baby without operation.

DR. COLLYER had noticed that after delivery women with retro-displacement and certain pelvic conditions had more or less waddling; also, that after symphyseotomy there was more or less mobility between the ilia up to the sixth or eight month, when tested with the patient resting first on one foot and then on the other; and in view of the pelvic disease in Dr. Garrigues's case he thought perfect union was interfered with and caused waddling until after the hysterectomy.

DR. GARRIGUES, replying to Dr. Vineberg's remarks, expressed the opinion that it would be a much more serious matter to make the vaginal incision in front of the uterus instead of behind, because of the danger of injuring the bladder, etc. Regarding the waddling gait, it might have been due to the occurrence of symphyseotomy and something else at the same time, but that the something else was the real cause seemed to have been proven by disappearance of the waddling after the second operation.

Case of Inversion of the Uterus. — DR. CHARLES JEWETT related the case. He had seen the patient with Dr. Ray on the 15th inst. She was a primipara, aged twenty-nine, had been delivered by Dr. Ray at 11 A.M., the 12th, after twenty-four hours' labor. There was profuse hemorrhage, but no shock. The uterus remained relaxed for some time. Ergot was given. The placenta was found in the vagina and was removed. At 1.30 P.M. the uterus was fairly contracted. Ergot was repeated in the evening. Next day rectal tube was used to relieve tympanites. The temperature rose on the 15th, and Dr. Ray found the uterus in the vagina, completely inverted. Dr. Jewett saw the patient late in the afternoon, the temperature was 103.2° F. After thoroughly cleansing the surface of the uterus, an attempt was made to reduce it under chloroform. First, pressure was made against the fundus with the finger, but as this proved too tiresome, a clean potato-masher was used, a bundle of gauze intervening between it and

the uterus. Reduction having been effected, gauze was introduced into the cavity of the uterus and vagina. The patient did well at first, but died of septicæmia about the fifth day, there being no evidence of septic foci outside the uterus. Dr. Jewett thought hysterectomy should have been performed as soon as it was seen that the patient was not doing well. Points of interest were the occurrence of spontaneous inversion several hours after labor, absence of material shock, absence of pain.

Dr. H. T. Hanks suggested that since the uterus was so large, the possible explanation of the case was partial or complete paralysis of the cervix.

Dr. R. A. Murray thought it not unlikely that version was frequently due to the faulty way in which the nurse or physician compressed the uterus after delivery. According to his observation, they almost universally simply indented the fundus with the fingers, instead of grasping the entire fundus and squeezing it.

Dr. Marx thought that in all cases in which the uterus did not show a tendency to contract it should be stuffed with iodoform gauze. Had that been done, he thought, inversion would not have taken place in the case related.

Dr. Collyer thought a tendency to fat, or fatty degeneration, caused relaxation of the tissues and favored inversion of the uterus.

Dr. Jewett said there was, no doubt, relaxation in this case. Sepsis had been established before reduction, as shown by the temperature, etc.

Symphyseotomy in a Tenement-house.—Dr. Herman L. Collyer read the paper and reported a case. The success of symphyseotomy, he said, depended upon accurate diagnosis, early performance, correct technique, prevention of sepsis, all of which could be carried out at the patient's home, even though it were a tenement-house. The risk was no greater than in hospitals, except with regard to sepsis. The antero-posterior contraction ought not to exceed two inches and a half, and the separation two inches and a quarter or a half. Greater separation was attended by great risk to the sacro-iliac synchondrosis and the soft tissues. Two factors determined the immediate results, namely, elective operation and antisepsis. The author preferred subcutaneous or post-pubic section. After describing the steps of the operation, he urged care on dividing the subpubic ligament, lest there should be too great separation. At this stage there was considerable hemorrhage, which could be controlled by the insertion of gauze. The child could be turned or the forceps be applied, at the option of the accoucheur. Care should be taken to prevent bruising of the soft tissues between the edges of the pubes. At the end of labor a strip of gauze was inserted at the lower angle of the wound, and the edges of the wound were stitched with silkworm gut. Reunion was best accomplished by a strap and perfect rest from two to four weeks.

Dr. Collyer's case was in a woman who, about a year or two before, had been delivered of a mutilated child after numerous attempts at extraction by several physicians. The soft parts had been injured also. During the next pregnancy she consulted him, November 15, 1893, and it was arranged to do symphyseotomy near term. The pelvic measurements were as follows: External, from crest to crest of the ilia, 10.5 inches; spine of the ilia, 8.75; spine of pubes, 5; crest to the pubes, 7.75; trochanters, 12; external conjugate, 7.75; internal conjugate, 3 inches. June 5th, aided by Dr. Grandin, in an apartment-house, patient anæsthetized, os dilated manually, head in left occipito-anterior position; pubes shaved, parts cleansed thoroughly; incision made over the vesical space; went down with blunt hook and finger to region of triangular ligament; hemorrhage speedily checked by gauze; divided the ligament; the joint was permitted to separate about two inches. Dr. Grandin ruptured the membranes, performed version, and extracted a child weighing nine pounds. Recovery was uninterrupted. Slight sloughing at one of the stitches, which readily healed. The child's head was measured and found too large to have passed the pelvic outlet: Biparietal, 4.25; occipito-frontal, 5; occipito-bregmatic, 4; bitemporal, 3.25.

The author said that this case and others of symphyseotomy in tenement-houses — Edgar, Coe, Garrigues, Murray—proved the feasibility of the procedure under such circumstances.

Dr. Garrigues would deny absolutely that it was as well to do symphyseotomy in a tenement as in a hospital. There were so many advantages in a hospital that it would be better to put the patient into a carriage, even while in labor, and take her there. Everything which one touched in a tenement was not only not aseptic, but was not passably clean. Nor was the operation always easy; sometimes it was quite difficult even for the experienced. At least two good men were necessary, and three or four assistants.

Dr. Charles Jewett said he had had all the experience he wanted with operations in tenement-houses. The objection to such surroundings pertained even less to the operation than to the after-care.

Dr. P. A. Harris said that while the operation could be done in a dirty house, it would be at considerable expense to the operator if he cared for success. It would be cheaper for him to hire a hall in the neighborhood and fit out a temporary hospital! In a tenement the rooms were dirty; the patient was dirty; everything was dirty; articles were required which were neither in the house nor in the neighboring houses. Regarding purely elective symphyseotomy, it should be borne in mind that it was not so much a question of the diameters of the pelvis as of the size of the child which was to pass through, and unless we were willing to wait until the second stage of labor, we would be likely to perform symphyseotomy unnecessarily, simply because the pelvis was more or less contracted and the woman had had difficulty at a previous labor, forgetting that the child might have been much larger than the present one would prove to be.

Dr. Marx did not believe that mortality statistics, thus far, justified us in calling symphyseotomy a safe and conservative operation, at least when compared with induction of premature labor; and in his opinion Dr. Collyer should have resorted to the latter, especially inasmuch as the patient lived in a tenement.

Dr. Vineberg admitted that the operation was safer in a hospital, yet he had obtained as good results in many gynecological operations in tenements as could be shown by hospital statistics.

Dr. Collyer thought it was the men connected with hospitals who refused to do operations in tenements. Such a practice tended to pauperize the community. As to induction of premature labor in preference to symphyseotomy, it must be remembered that the nearer term a child was born the better were its chances of living.

Does Laceration through the Sphincter Ani ever Occur in the Median Line? Sixteen Cases of Lateral Injury.—Dr. Robert L. Dickinson read the paper and illustrated on the board and by chart. In 16 cases of sphincter injury seen soon after labor, no laceration in the median line was found, and but 2 near that point. In 8 of the cases the tear of the external sphincter occurred from seventy to ninety degrees from the median line. In 12 of the cases the anterior end of the torn muscle was rooted out of its sheath and hung bare, while the sheath presented a well-defined pocket or pit. In late secondary operations the lateral character of the injury was difficult to detect. There were anatomical reasons for the laceration at this point under the conditions found during maximum distention. Since the time, in February, 1887, when a striking case of recent lateral injury to the anal sphincter drew his attention to the matter, the writer had looked in vain for a case

of laceration in the median line. The cases, with a few exceptions whereof the notes were lost, seen within one or two weeks of delivery, had been carefully noted and sketched, and were reported in the paper. In all, œdema or rigidity of the pelvic floor, or violence during delivery, explained the injury.

The vaginal laceration and the anal injury might be on opposite sides. The method of repair consisted in two buried catgut sutures carried through the free hanging end of the muscle and then down into the pit to catch the hidden end, drawing the torn parts in accurate apposition. The rest of the injury was then repaired as usual, taking care that one of the external silkworm sutures supplemented the catgut in the sphincter.

It would be seen from this study of fresh tears of the external sphincter, that it was not sufficient in old injuries to make a simple denudation and unite. A careful study of the topography was necessary, one had to hunt for the point at which the muscle had parted, and dig for the end which had drawn itself within its burrow. The contraction and atrophy might be considerable and make the search difficult.

Dr. Jarman had thought one should take into consideration the fact that the injury was lateral, not median, in making secondary repair. He had not known, however, that the tear was always lateral. The pit, referred to in the paper, should be a landmark in operating.

Drs. Murray, Vineberg, and the author made a few remarks on the method of operating.

Election of Officers.—Dr. H. C. Coe was elected Chairman, and Dr. G. W. Jarman Secretary, for the ensuing year.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, January 28, 1895.

Egbert H. Grandin, M.D., President, in the Chair.

Anæmia in Children.—Dr. Frederic M. Warner read a paper on this subject. (See p. 231.)

Dr. J. H. Fruitnight had found citrate of iron in moderate doses well borne by children. Arsenic was very valuable, and he had obtained benefit from oxygen in several cases.

Dr. Bishop preferred Zeiss's hæmacytometer to Gowers's, and said it should be used from week to week in cases of anæmia, in order to appreciate the effect of treatment. When one used such an instrument he lost confidence in his ability to judge of anæmia by the appearance. A great deal of iron was administered unnecessarily because physicians did not employ this simple and accurate means by which to judge of anæmia. The amount of dentistry caused by giving tincture of chloride of iron was enormous, and could be quite avoided by giving Blaud's pills, which were just as useful in any but the acute form of anæmia.

Anæmia and Chorea.—Dr. A. D. Rockwell called attention to the liability of anæmic patients to chorea, especially under such exciting influence as fright. The lowered condition of the blood-supply seemed to influence the cerebral cortex, and in that way induce the chorea.

Anæmia an Expression of Rickets and Arrested Development.—Dr. Mary Putnam-Jacobi thought anæmia in children was nearly always an expression of rickets and of arrested development. It might be compared with the chlorosis of adolescence, since both implied that development was irregular, and had not been met by sufficient force of nutrition. The elimination of the process of growth in adults made a very great difference between anæmias occurring at this time of life and in childhood. The reader had not spoken of cod-liver oil and the lime salts. These often made it unnecessary to give iron to children at all.

Dr. R. A. Murray thought the process of growth was a fact ever to bear in mind in discussing the anæmias of children. Iron, cod-liver oil, arsenic, and mercury appealed to the nutrition. In institutions they wrapped young anæmic children in cotton soaked with cod-liver oil, with the result that daily improvement could be seen in their condition. There was clinical ground for the use by the old physicians of small doses of bichloride of mercury as a tonic. Where there was tendency to rheumatism, iron seemed even to precipitate a rheumatic arthritis.

Elective Accouchement (So-called Accouchement Forcé): Its Advantages.—Dr. L. M. Michaelis read the second paper of the evening (see p. 228).

Condemns the Bougie; Commends Barnes's Bag.—Dr. Ralph Waldo had been highly pleased with that part of the paper which condemned rupture of the membranes and introduction of bougies. He termed the latter a relic of barbarism. If there were no great urgency for immediate dilatation and delivery, he would prefer Barnes's bag to manual dilatation. The bag filled with water tired the cervix better, and was attended by less danger of tear.

Dr. R. A. Murray thought dilatation could be accomplished much better and sooner by the hand than with Barnes's bag, and the method was attended by less danger of sepsis.

Commends the Bougie; Condemns Barnes's Bag.—Dr. E. A. Tucker differed decidedly from Dr. Waldo, who had spoken of the bougie as barbarous, for he had employed it with satisfaction in fifty or seventy-five cases the past five years. He thought Barnes's bag rather was a relic of barbarism. There were some disadvantages to the bougie. Accouchement forcé was a valuable method, but if it were employed universally he thought the results would not by any means be so uniformly successful. It would probably result in sepsis and deep tears in the hands of some. With proper care the bougie should not cause sepsis, and he was unable to comprehend how it could have caused rupture.

Dr. Marx was glad to see so conservative a man as Dr. R. A. Murray come over to the side of the President, Dr. Grandin, who had read the first paper on the subject of accouchement forcé over two years ago, and was soon followed by Dr. Marx. They were told that they would murder some women, but two years had elapsed and no murder had yet been committed. On the contrary, lives had been saved where formerly they had been lost. He knew of but one contra-indication, and that was cicatricial stenosis of the os. In that condition Dührsen's cutting operation was indicated.

Dr. Feinberg hoped the paper would lead to the more general adoption of this method. He thought the woman should be anæsthetized during the first as well as during the second step. He had met with one case, without cicatricial stenosis, in which he was unable to dilate with the fingers, and Dr. Grandin then tried and also failed.

Dr. Fruitnight related a case of placenta prævia in which manual dilatation was practised, and mother and child were saved. Barnes's bag should be relegated to barbarism.

Dr. A. F. Currier had seen a number of cases of rigid os in which forcible dilatation by the steel dilator was best. Manual dilatation in primipara might in some cases be extremely difficult, if not impossible.

Dr. Michaelis said he had expected his paper to meet with tremendous opposition, while in fact it had met with none. Anæsthesia was unnecessary during the first step. It was not painful to wash out the vagina. In placenta prævia the depressing effect of the anæsthetic at this stage might bring on hemorrhage. While his own cases had occurred in multipara, he could see no reason why there should be difficulty in dilating with the tamponade and hand in primipara.

Incubator for Prematurely-born Infants.—Dr. Simon Marx demonstrated an incubator for raising pre-

maturely-born infants. It contained a heat-regulating apparatus or thermostat. The proper temperature was about 96° F. The manufacturers sold the incubator for twenty-five dollars.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, November 28, 1894.

GEORGE C. FREEBORN, M.D., PRESIDENT.

Calculus Pyelitis.—DR. H. P. LOOMIS presented an unusual specimen of calculus pyelitis. The patient, Kate B——, thirty years of age, had been under observation in Bellevue Hospital for two weeks previous to her death, and yet no symptoms had been detected indicative of the extensive kidney lesion from which she had suffered. There had been no frequency of micturition, and no albumin or casts in the urine, but pus had been found in moderate quantity. The history stated that she had been losing flesh and strength for the past two years, and had had repeated attacks of dyspnœa, palpitation, and precordial pain, with morning vomiting. She had also complained, particularly within the past two months, of severe pain in the back, shooting into the right side. Examination had shown her to be very pale, and the heart-action quite feeble. The patient was an alcoholic subject, and had peripheral neuritis, so her general condition was ascribed to alcoholism. She grew steadily weaker, and finally died of cardiac failure. At the autopsy, which was made twenty-four hours after death, the heart cavities were found dilated, but there were no valvular or arterial lesions. The liver was enlarged and fatty, but with these exceptions there were no lesions found outside of the kidneys. Both kidneys were moderately enlarged, and of a red color, and on section the renal substance was found to be almost entirely destroyed, its place being occupied by large cysts communicating in each kidney with an excessively dilated pelvis and calices. In places the cysts were only separated from the capsule of the organ by strips of kidney substance scarcely one-eighth of an inch thick. Both kidneys were about equally involved, and contained but very little normal tissue. The cysts contained a thin, turbid fluid, apparently urine with some pus. From eight to fifteen calculi were found in each kidney, and they were so large as to fill the pelvis, calices, and a number of the cysts in each organ. One large stone, the size of an egg, with rounded facets, filled the pelvis and a number of the cysts in the right kidney. The pelves of the kidneys showed none of the evidences of a pyelitis which could be accounted for as a primary condition. The microscopical examination of the calculi showed them to be composed entirely of uric acid. Many of the sections of the kidney showed a comparatively normal structure, while others revealed a moderate interstitial nephritis. Both ureters were dilated. The bladder was normal.

The speaker said that in his experience the formation of such a large number of calculi as a primary condition had been very rare. There was no pyelitis in this case except what had been set up by the irritation of the stones. The secondary retention cysts were due to the hydronephrosis caused by the obstruction which the stones offered to the outflow of urine, as they had moulded themselves into the shape of the pelvis or calices, and had extended into the elongated recesses formed by the dilated calices and cysts. Another interesting point was the absence of renal symptoms in this case.

DR. S. T. ARMSTRONG said that in all cases in which he had found dilated pelves at autopsy, he had also observed that the ureters were dilated. He had been unable to find an explanation of this fact.

Aneurism of the Left Ventricle in a Fibroid Heart.—DR. LOOMIS then presented this specimen. George H——, sixty years of age, had been admitted to Bellevue Hospital in an unconscious condition, with complete paralysis of the right side of the face, and of the right arm and leg. He died at the end of three days without having regained consciousness, so no history had been obtained. The autopsy was made ten hours after death and showed an extensive area of yellow softening in the brain, involving the internal capsule and a part of the temporal lobe. The arteries of the circle of Willis showed atheromatous and calcareous changes, and were extensively diseased. Examination of the small arteries in various parts of the body revealed the existence of a general arterial fibrosis. The kidneys were normal as to size, color, and adherence of the capsule, but the microscope showed moderate diffuse interstitial nephritis. The lungs and liver were normal. The heart was enlarged, weighing sixteen ounces, and was of firm consistence. On opening the left ventricle an aneurism was found to have burrowed nearly through the wall of the heart, leaving only about one-twelfth of an inch of muscle fibre intact. The diameter of the aneurismal pouch was about an inch and a quarter. Scattered through the hypertrophied wall of the left ventricle were white patches. One of these was as large as a cherry, and presented almost the appearance of a distinct tumor. Microscopical examination of a number of sections made through these patches, and through portions of the cardiac wall that appeared to be normal, revealed the lesions of a very widely disseminated and advanced interstitial myocarditis, which had entirely destroyed the muscle fibres in the white areas. The thin portion of the aneurismal sac was fibrous tissue, with only a few heart-fibres seen among the connective tissue. The valves of the heart were normal. The coronary arteries from their origin to their microscopical subdivisions showed all forms of arterial degeneration—calcification, atheroma, and fibrosis. The aorta itself was but slightly diseased.

The speaker said that this heart was interesting—1. On account of the extensive and general destruction of the new connective tissue, no portion of the wall of the left ventricle being free from this increase. 2. Because there was a fibroid myocarditis independent of, and not accompanied by, any changes in the endo- or pericardium. The new connective tissue had started from the interference of the circulation through the obstruction in the coronary arteries. 3. The white masses, appearing like tumors, were areas of dense new connective tissue. 4. The aneurism was one of the results of the destruction of the muscle-fibres, and the giving way of the heart-wall from chronic interstitial myocarditis.

Prostatic Abscess, with Resulting Thrombi in Right and Left Bronchi; Gumma of the Kidney.—DR. FARQUHAR FERGUSON presented the specimens. They were taken from John K——, aged fifty-six, who had been admitted to the New York Hospital on November 7, 1894. The history stated that he had had gonorrhœa for the first time about ten years ago, and that since that time there had been more or less discharge. Twenty-five years ago he had had syphilis. For the past four years he had noticed some difficulty in urination, and more or less incontinence. Three months ago a painful mass had been first noticed in the perineum. This had proved to be an abscess, which had opened spontaneously. Since that time most of the urine had been discharged through this opening. Later on, another perineal sinus had formed more anteriorly. At the time of his admission to the hospital, most of the urine was passed through these sinuses; his urine was cloudy, and contained pus and about five per cent. of albumin. Physical examination showed the upper half of the glans penis to have been eroded by a chancre, and the whole region to be in a more or less cicatricial condition. A No. 23 sound was passed into the bladder. In the anterior part of the perineum, on the right side of the base of the scrotum, was a

sinus, two and a half inches deep, which communicated with the urethra. Well back on the left buttock was another sinus, also discharging urine. On November 14th, under ether, Dr. Stimson laid open the sinuses, curetted them, and packed the wounds with iodoform gauze. On each of the two succeeding days the patient had a chill. The wounds looked fairly healthy, and more urine was discharged through the natural channel than had passed for some time previously. Three days later he was up and around the ward. On the evening of November 24th he had another chill, followed by a temperature of 101.8° F.; his pulse was almost imperceptible, and his breathing very labored. On November 26th he was again about the ward, but in the early part of that evening he suddenly fell dead. The autopsy showed a large abscess cavity, filled with pus, situated behind the prostate. The bladder was enormously hypertrophied, and the urethra showed strictures and evidences of false passages having been made. There was a moderate dilatation of the pelves of the kidneys. A thrombus was found in the right and left bronchi.

Tuberculosis and Sarcoma.—Dr. Ferguson then presented specimens showing tuberculosis and sarcoma in the same individual. Mary S——, sixteen years of age, a Syrian, had been admitted to the hospital on February 19, 1894, with the history of having had a swelling on the left side of the neck for the past three years. This swelling had been incised on two occasions, and had continued to discharge. One month before admission a swelling had appeared on the right side of the neck. Two years before, the left elbow had become somewhat enlarged and painful. On admission, the physical examination showed the left side of the neck to be the seat of a swelling which extended from the ear, below the jaw, nearly to the median line, and down to the clavicle. There were three granulating areas. On the right side of the neck was a tumor about the size of an egg. There was also a slightly tender swelling on the ulnar side of the left elbow. On February 21st an extensive dissection was made of the left side of the neck, and the glands removed. On account of the amount of skin necessarily removed at the operation, the wound healed largely by granulation. Eighteen days after the operation, acute pain and swelling developed in the left elbow, and three days later, March 14th, the elbow was incised, and a large amount of grayish and fatty degenerated tissue was dissected away. It completely surrounded the ulnar nerve for two or three inches, and extended under the posterior fascia up to the olecranon, and into the extensor muscles of the forearm. The wound was partly stitched, and partly packed with iodoform gauze. With the exception of two small sinuses the wound was entirely closed three weeks after the operation. On April 6th the glands were dissected away from the right side of the neck. On April 27th it was noted that there was a sinus in the arm and in the neck, and that the left ankle had just become swollen. It was at once encased in plaster of Paris. On May 23d an abscess of the ankle was opened. On May 30th it was noted that the recurrent tumor in the left elbow was rapidly enlarging. On July 9th the history states that there was an abdominal tumor reaching up to a point between the umbilicus and the ensiform cartilage. By July 23d the sinus in the neck and elbow had closed, and the entire abdomen a curved line from the eighth rib to two inches above the umbilicus, and to the middle of Poupart's ligament, on the left side, was the seat of a tumor. The patient was then sent into the country. On her return, September 1st, she was greatly emaciated; all the tumors had increased in size, and in addition there were six subcutaneous nodules in the abdomen and chest. She died on November 28th.

This woman, at the time of her admission to the hospital had had typical tubercular glands of the neck; and the gross appearance of the tissue removed from the elbow was also that of tubercular tissue, but the microscopical examination showed it to be typical sarcoma. After death all the tumors were removed. There were sixteen of them in the abdominal wall. Undoubtedly, the speaker said, this girl had had both tuberculosis and sarcoma. The tumors had involved the ovaries, but not the uterus. The more recent tumors of the neck were secondary sarcomata. The kidneys showed several nodules, which would probably prove on further examination to be sarcomatous.

The Society then went into executive session.

Stated Meeting, December 12, 1894.

George C. Freeborn, M.D., President.

Ruptured Aneurism of the Arch of the Aorta.—Dr. Pearce Bailey presented, through the courtesy of Dr. Hodenpyl, specimens from this case. A man, aged fifty-nine, came to Roosevelt Hospital last October. Three months before he had become overheated, and had been in the Presbyterian Hospital for five hours. On leaving that hospital, he had complained of some pain about his chest. On entering the Roosevelt Hospital, in October, he was suffering from a paraplegia which had occurred very suddenly and without apparent cause. Examination showed loss of knee-jerks, and control of the bladder and rectum, and anæsthesia below the mid-thoracic zone, but extending irregularly from the fourth intercostal space on the left side, and the fifth intercostal space on the right side. Examination of the urine was negative. He died a few days after admission. The house-staff were positive that there was no circulatory cause of death. At the autopsy, the spleen and the liver were found in a condition of chronic venous congestion, and the kidneys were the seat of chronic diffuse nephritis. The lungs were apparently normal. The left pleural cavity contained about one pint of clear serum. There was a very little fluid in the right pleural cavity, but at the bottom of this cavity there were about two quarts of blood-clots. At the lower and posterior part of the arch of the aorta, was an opening measuring about 1½ × 1 inch. It had rounded edges, and communicated with a thick aneurismal sac. The aneurism had eroded the adjacent vertebræ. The heart was of about the normal size. There was atheroma of the coronary arteries and of the abdominal aorta. On opening the spinal cord by the posterior method, a firm blood-clot was found embedded in the dural fat. It was situated on the posterior surface of the dura at a point corresponding to the third, fourth, and fifth dorsal segments, and was distinctly circumscribed. Underneath this clot at the fourth dorsal segment of the cord was an area of necrosis.

From the nature of the aneurismal opening, and from the fact that there was clear serum in the upper part of the pleural cavity with clotted blood lower down, it was evident that the aneurism must have ruptured some time before death; yet the patient had not given any definite symptoms of such a condition. Was it possible that the aneurism had ruptured three months previously, while he was at the Presbyterian Hospital? It was also interesting to note that on the left side the clot was below the third, fourth, and fifth segment, and that on that side of the body the anæsthesia extended about two inches higher than on the other side.

Double Empyema; Acute Lepto-meningitis; Large Meckel's Diverticulum.—Dr. George P. Biggs presented several specimens from a case giving the following history: A male, aged fifty, had been found in a lodging-house on the same day on which he had died. It was stated that he had walked into the house on the night previous. When found he was semi-comatose; there was marked rigidity of the muscles of the back of the neck; the pupils were symmetrically contracted, and not responsive to light. Pus was found in both

pleural cavities. The man died while preparations were being made to evacuate the pus by rapid incision. At the autopsy, which was made twelve hours after death, the rigor mortis was extremely slight. There were two quite superficial recent abrasions over the second toe, and one over the right knee. The abdominal cavity was normal, with the exception of a slight recent perihepatitis. The diaphragm was depressed about one space on each side. Each pleural cavity contained about fifteen hundred cubic centimetres of sero-purulent fluid, and the lower and posterior portions of both lungs were covered with very thick layers of purulent fibrin. The layer over the right lung was fully one and a half centimetre in thickness. The lungs were adherent posteriorly, and during life gave rise to numerous râles over the posterior portion of the chest. On cutting open the lungs, the upper half of the upper lobe of the left lung showed a mass of fibrous tissue, with cheesy areas scattered through it, showing the existence of an old tuberculosis. In another portion of the same lung were several small, grayish, shot-like tubercles, evidently of very slow growth. Similar lesions, though of less extent, were found in the apex of the right lung. The vessels were free from thrombi, and there was no œdema. The pericardial sac was greatly distended with thin pus, and both surfaces of the pericardium were covered quite thickly with purulent fibrin. The clinical record showed that the heart-sounds had not been particularly feeble, and that there had been no friction-sounds heard.

In the same case there was an acute lepto-meningitis, involving both the brain and spinal cord. The exudate was over the entire surface, but was most abundant over the vertex and median surface. An unusual quantity of sero-purulent fluid escaped on incising the brain. The velum interpositum contained considerable pus, and there was a small amount of purulent fluid in each lateral ventricle. Examination of the fresh blood from the brain and pericardium showed in the former an unusually large number of diplococci with distinct capsules. In the fibrin from the surface of the lung and from the pericardium, a few of these only were found.

An unusually large Meckel's diverticulum was present in this case. It was about two feet from the ileo-cæcal valve, and was 14 ctm. in length and 3 ctm. in diameter. There were a number of small secondary diverticula near the termination. At the hepatic flexure of the colon were four pigmented cicatrices, ½ to 2 ctm. in diameter, and feeling more or less nodular.

Encapsulated Empyema; Ulcerative Endocarditis; Renal Calculus.—Dr. Biggs also presented specimens from a second case. This patient was a female, forty-five years of age, who first complained of sickness about five weeks before she came under observation at the New York Hospital. On admission complained of pain on the right side with dyspnœa, and of cough with mucous expectoration. There was no chill or fever, and she did not take to her bed until about three weeks before death. On entering the hospital her temperature was 100.6° F., respirations 36, and pulse 136. At this time there were signs of fluid in the right chest; the heart was intermittent and very feeble. The right chest was aspirated, and seventeen ounces of purulent serum withdrawn. The temperature then rose to 103.4° F. The chest was accordingly incised and drained. Examination of the urine showed a trace of albumin with granular casts. The temperature still remained between 104° and 105° F. after this drainage of the chest; she developed slight delirium, and finally died twelve hours after the operation. At the autopsy, a double empyæma was found. The cavity which had been drained was free from fluid, but there was considerable fibrin. On the left side there was an encapsulated empyema over the middle of the lower lobe, containing about six ounces of pus. The heart was slightly dilated. The left ventricular wall was very slightly hypertrophied. The tricuspid, mitral, and aortic valves were perfectly normal. On two of the cusps of the pulmonary valve were large thrombi, with ulceration of the under surface of the valve. The largest thrombus had a diameter of 2 ctm., was very firm, and distinctly laminated. The lungs were congested and œdematous, and there was some hypostatic consolidation of the posterior portions. The spleen was two and one-half times its normal size, and quite soft. The left kidney was much larger than normal, the capsule was slightly adherent, the surface was finely granular, and the cortex showed many cysts. The right kidney was surrounded by an unusually thick layer of adipose tissue. The kidney appeared outwardly to be about normal, except that its capsule was adherent. The pelvis was considerably dilated, and contained a calculus, 4 by 1¼ ctm., one end of which fitted into the opening of the ureter. Around the pelvis was a thick deposit of solid adipose tissue between the pelvis and the kidney-tissue proper. The latter formed a ring only about three-quarters of a centimetre thick at the surface.

Tumors of the Skin—Mycosis Fungoides.—Dr. Biggs next presented some unusual tumors of the skin. They had been removed from a married woman, thirty-five years of age, whose family and personal histories were negative. About four years before coming under observation at the New York Hospital, she had first noticed an eruption on the legs, arms, and back, which was described as consisting of red pimples slightly depressed in their centres. These had grown slowly until some of them had reached the size of a hen's egg. Some had disappeared spontaneously, it was said, leaving a copper-colored stain, while others had ulcerated. The urine had been normal; the temperature 99.2° F., the pulse 80, and the respirations 20. At the time of admission, examination showed an immense number of reddish non-indurated spots on the legs, and a few on the back. There were twenty to thirty nodules, varying in size from a pea to a hen's egg, and ulcerated on their flattened surfaces. The large ones were found chiefly on the legs, thighs, and hips. They were all very freely movable, and slightly constricted at the base. The glands of the groin and axilla were enlarged. A number of the large tumors were removed from different situations. About two weeks after this, the history stated, two tumors had nearly disappeared spontaneously, and two weeks later, some new tumors had appeared.

Three of these large growths were presented to the Society. One had a diameter of 8 ctm., and was elevated about three centimetres above the surrounding skin; another was 5½ ctm. in diameter, and the third was 3 ctm. in diameter. In the fresh state they were red over the surface, and appeared to be superficially ulcerated. On incision, they were found to be of firm consistence, grayish in color, moderately vascular, and not degenerated in any portion. Microscopical examination showed that the epidermis was not involved except where ulceration had occurred, the process having been in the derma and subcutaneous tissue. In structure they consisted mainly of small round cells with a small amount of young connective tissue mixed with them. The blood-vessels had quite thin walls. The appearance was not unlike that of some cases of apparently simple adenitis. It also bore a striking resemblance to a sarcomatous growth, so that it had been a matter of dispute whether these growths could be distinguished from sarcomata. Those who claimed to distinguish between the two, said that the clinical history was different—the condition beginning as an eruption not unlike lichen planus, and the fungoid growths not developing for some time afterward. Another distinguishing point was the spontaneous disappearance of some of the tumors, eventually leaving not even a copper-colored staining. If no complication occurred, death resulted in these cases from progressive anæmia or from the development of leukæmia.

A few observers had found the condition associated with a micrococcus, but many other observers had not found them present.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

DR. JAMESON, C. B., THE SOUTH AFRICAN ADMINISTRATOR — DETACHMENT OF RETINA—MALINGERING—PARALYSIS OF DIAPHRAGM AFTER DIPHTHERIA—INTESTINAL OBSTRUCTION FROM GALL-STONES — HEALTH OF LONDON.

LONDON, February 2, 1895.

DR. JAMESON'S distinguished career as a South African "Administrator" is naturally a source of congratulation by his professional brethren, especially those who knew him in earlier days. This feeling has led to his being entertained at a dinner got up in his honor by his old teachers and fellow-students of University College, where he obtained no little credit during his curriculum and competed successfully against Mr. Pepper for a residential appointment. Mr. Christopher Heath took the chair at the dinner, where Sir Russell Reynolds and other teachers of Dr. Jameson were present. In returning thanks for the toast of the evening Dr. Jameson was very happy in the way he assured his hosts that whatever political views might be held and whatever public opinion might eventually obtain, he was most anxious that his profession should understand the origin of what took place, how for three years everything possible had been done to avoid a conflict, how he hoped to the last it would still be avoided, and that no one could be more ready than he was to condemn any attempt to bring on a conflict with these unfortunate races.

On Monday Dr. Jameson gave an address at the Imperial Institute to a distinguished audience, between two thousand and three thousand in number, presided over by the Prince of Wales. The doctor gave a glowing account of the territories of the chartered company, where whites can live in health and rear their families, and where there is plenty of room for our overflowing population, and prosperity awaits their arrival.

Sometimes the course of retinitis in cases of granular kidney is very rapid, though in others dimness of vision may not be complained of. The prognosis, however, of albuminuric retinitis in any form is generally grave. Occasionally detachment of the retina occurs, and Dr. Samuel West related two cases of this lesion at the Clinical Society last Friday. He drew attention to the suddenness of the onset of failing vision; for a patient may become blind in a few days after first perceiving any dimness. It must be admitted that detachment of the retina is very rare compared with hemorrhage, though one of Dr. West's cases was complicated by purpura; thus showing a hemorrhagic tendency.

Dr. Semon related a rather curious case of malingering in a lady, thirty-six years of age, who inflicted injuries on her throat, apparently for the sake of exciting sympathy. There seems to be no doubt about the origin of the injury, and the patient had formerly been seen by Mr. Hutchinson for injuries about the breast, which he was convinced were artificially produced. Some other cases of malingering were mentioned by other speakers, after which a paper was read by Dr. Pasteur on respiratory paralysis associated with cardio-pulmonary symptoms in diphtheritic paralysis, based on 32 cases in the Northeastern Children's Hospital. In no less than 29 of these cases the diaphragm was paralyzed and 16 of them died. This is certainly a very large proportion, and the author found that the diaphragm might be affected with paralysis coming on insidiously as a part of the peripheral palsy, or it might come on acutely as a part of a bulbar crisis. If such experience is general, the mortality of diphtheritic paralysis is probably higher than commonly supposed, as the fatal symptoms might not be attributed to the primary disease. Certainly, recovery from bulbar crisis must be very rare, and the supervention of respiratory trouble would indicate the gravest prognosis. If paralysis of the diaphragm lasted for two days, Dr. Pasteur found collapse of the lung very likely to occur, giving rise to definite physical signs, the base of the right being more frequently affected than that of the left lung. Many of his cases were verified by autopsy, and all were excluded in which there was any doubt as to the paralysis of the diaphragm. A good deal of surprise was nevertheless expressed at the large proportion of recoveries from a lesion which is generally observed to be fatal, and there is no doubt that it may occur later than is often supposed, coming on quite suddenly, six, eight, or nine weeks after the primary disease.

At the last meeting of the Royal Medical and Chirurgical Society Mr. Mayo Robson read a paper on the varieties of intestinal obstruction due to gall-stones, which he classified thus: 1. Dependent on local peritonitis in the region of the gall-bladder leading to paralysis of the bowel. 2. Volvulus due to violence of the colic induced by the passage of a large concretion through the small intestine. 3. Mechanical obstruction by a large concretion. 4. Obstructions by adhesions or stricture, the result of past attacks, or of healing fistula. Two cases were related of the first kind, then two of the second. While as to impaction, communications from institutions receiving eighty thousand patients gave only four cases in the last twelve months, showing that even this form, though the commonest, is certainly rare; a conclusion which agreed with the statistics of other speakers. Mr. Robson considered recovery from volvulus scarcely possible except by operation, and that statistics earlier than two years ago could not give such results as may now be obtained, still less as we anticipate in future. At the same time he admitted that if all surgeons operated as routine treatment increased, mortality might follow.

The President (Mr. Hutchinson) regretted the author had not collated the successes in recent years, and said that up to this time one-half of his cases died after operation, and he was inclined to think that even when death threatened, the chances of recovery were about equal if operation was refused. He hardly thought the third class supported the proposal for operating, and he mentioned another class which had not been alluded to, viz., cases when a gall-stone remained for months in the intestine, giving rise to repeated attacks of obstruction. He spoke of two such cases, both of which eventually passed the stone without assistance, and remarked that he had never seen in the autopsy-room an impacted stone which had caused death. Another speaker had previously remarked that he had only seen one impacted gall-stone in the course of eight hundred autopsies, but I believe there are a few specimens scattered among the pathological museums.

The health of London is improved. Last week the mortality from diphtheria fell to twenty-nine, just one under the corrected average for ten years.

The British Institute is now supplying antitoxin.

The British Pharmacopœia is apparently as perfect as, and more tangible than, the British Constitution. In a heated discussion before the General Medical Council concerning the need of a revision, one speaker after another declared it to be the best pharmacopœia ever published, and the general opinion seemed to be that it would be as wicked to revise the pharmacopœia as to revise the prayer-book.

A HYPNOTIZED MURDERER.

To the Editor of the Medical Record.

Sir: Referring to your editorial in the Medical Record of January 12, 1895, entitled "A Hypnotized Murderer," it fell to my lot to be a witness in this case, at the coroner's inquest, the preliminary, and at the final trial in the District Court. I was called to attend the murdered man, Thomas Patton. The subject of hypnotism was not suggested until after the jury in the case of the State against Anderson Gray had rendered their verdict, which was murder in the first degree; but during or after the trial of Macdonald, who was cleared and whose case immediately followed that of Gray, some enterprising newspaper correspondent sprung the hypnotism theory; the wide publication of the matter came about in this way; no evidence was introduced during the entire trial tending to show that Macdonald had been hypnotized. Gray was convicted upon the ground that he was an accomplice in the murder, that he influenced Macdonald to do the shooting.

I am yours very truly,

R. A. McIlhenny, M.D.

Conway Springs, Kan., January 31, 1895.

THE NATIONAL HEALTH BUREAU.

To the Editor of the Medical Record.

Sir: It is earnestly to be hoped that legislation for the establishing of a national department of health, or a national health bureau of some kind, will not be jeopardized, or entirely defeated, in the present Congress by differences among medical men as to the proper scope and character of the proposed law. The details of the scheme are of minor importance, and it would be well for medical men to waive somewhat of their preferences and endeavor to unite upon that which seems most feasible, rather than divide upon different measures and, by want of unanimity, secure nothing. [The session of the present Congress ends in about four weeks from now, and if no action be taken before March 1st, the question goes over to another Congress, and nothing may be done for two years or more.]

The importance of this measure can hardly be overestimated. Nothing is of more importance than the health of the people, and there is every reason why there should be in the general government a department or bureau charged with the duty of investigating the causes of disease, especially of epidemics, the collecting of statistics of disease, health, and mortality, and reporting upon all facts bearing upon the sanitary conditions of the people. And no one who has had occasion to examine the statistical reports of the health boards in different cities and States of the Union need be told how imperfect, confusing, and unsatisfactory they are. One of the first good results of the proposed department would be something like order and reliability in the reports from different parts of the country in the matter of disease and mortality, instead of the present incomplete conglomeration.

The President of the United States has, in his late message to Congress, recommended the inauguration of a national board of health, "or similar national instrumentality," and a bill to that end is now before Congress. The scope of this bill is none too broad, nor its powers too great, for the work of collecting and collaborating reliable data as to the sanitary conditions in all parts of the country and presenting them in intelligible form as a basis for the action of local health authorities or of Congress. Out of such a department we might expect to grow an institute similar to that founded at Berlin, under a special act of the German government, for experimental investigations in the line of bacteriology. A large part of the work on the antitoxin treatment of diphtheria has been done in that institute, or in connection with it. New discoveries in this direction are certain to be made, and we should have a national laboratory for such investigations. If a national board of health were to give its endorsement to antitoxin treatment in diphtheria, and stand ready to furnish from its laboratory the immunizing serum, then its use in the treatment and prevention of this disease throughout the country would become general, and the neglect to use it, should epidemics of diphtheria occur, would be almost criminal.

Those who have this matter in charge should rouse themselves and push it at once and vigorously in some shape. If we cannot get the ideal measure, let us have what we can get.

Leonard Landes, M.D.

New York, February 2, 1895.

A MAN WITH FOUR TESTES.

To the Editor of the Medical Record.

Sir: In mentioning the following fact to a physician, he asked me to write of it to you, as a matter of interest to the medical profession.

As the recruiting officer of the United States Army at this point, the duty of making medical examinations of applicants devolves on me. In a recent examination of a recruit I found he had, as I supposed, three testicles. Knowing that it would interest a physician, I took the man to one, who found that the fellow was better off yet—he had four. Three were on the left side of the scrotum, and one on the right. They were all apparently perfect testicles, and gave the peculiar pain incident to pressure. Three were large and well-developed, and one, situated high up in the scrotum, was small.

There appeared to be but two spermatic cords, though the two large testicles in the left side seemed connected by a subsidiary spermatic cord, which I suppose would indicate that one was supplied from the other.

Yours truly,

Alex. M. Davis,
2d Lieutenant, Eighth Cavalry,
Recruiting Officer.

Fort Wayne, Ind., January 29, 1895.

THE SIN OF SUBSTITUTION.

To the Editor of the Medical Record.

Sir: Physicians all over the country are complaining of the "sin of substitution" practised by druggists, yet, notwithstanding this universal complaint on the part of physicians, they do not begin to realize the extent to which substituting is indulged in by druggists.

It is impossible for physicians practising in large towns or cities to "follow up" their prescriptions as closely as those who are located in smaller towns, as the former do not meet their patients in a social or casual way nearly so often as the latter; and, indeed, not more than perhaps fifty per cent. of the patients of the busy city doctor are personally known to him, and not one time in a hundred has he the opportunity of knowing whether his prescription accomplished its purpose or not. It is different with the doctor living in a small town; if the medicine he prescribes does not do its work he hears from his patient "in no uncertain tones," and how often have I investigated under these circumstances and found that the medicine prescribed had not been put up by the druggist, but a substitute instead.

Not long ago I had occasion to repeat for a little patient a prescription of elix. pepsin and bismuth; as the little patient and her mother were about to start for a visit to San Francisco and had not the time to have the prescription filled by the home druggist, it was taken to San Francisco and filled by one of the best known druggists of that city. When the mother went to give a dose of the medicine to the child it was

so unlike that which had been previously prescribed that she refused to use it, and on her return home brought the bottle of medicine with her and immediately sent it to my office for examination. I found it to be nothing more than a simple elixir containing a little subnitrate of bismuth and a little powdered pepsin. It might have answered the same purpose as the preparation I prescribed, but it was not what the prescription called for.

Again, not long since I had occasion to prescribe for a child suffering from indigestion, with instructions to have the prescription repeated as long as the child needed it. It was properly filled the first and second times; the third time it was filled it seemed not to have the desired effect, the child got quite sick and I was sent for. I asked to see the medicine and on examination found it not to be what the prescription called for. I sent the bottle to the druggist with a message to put up the preparation my prescription called for, and no other. The patient began immediately to improve, and soon recovered from the attack of indigestion. I afterward found that the druggist had substituted his own preparation, a very good imitation so far as color and general appearances were concerned, but utterly worthless as a medicinal preparation.

I could give many instances such as these that have come to my knowledge, not only in my own practice but also of other physicians, so I think I am correct in presuming that similar substitutions have often occurred when I had no opportunity of tracing them up. My experience with the average druggist leads me to conclude that his reliability is about on a par with that of the butcher and milkman.

Now what is the remedy for this appalling and unfortunate state of affairs? There are two, and I think only two.

First. The physician can keep his own drugs and compound his own prescriptions, but this is possible only with the country doctor or those located in small towns. With the physicians living in large towns and cities it is impracticable and not to be considered.

Second. For the benefit of the city physicians I propose the following plan: Let the physicians form a joint stock association for the purpose of owning and operating a certain number of drug-stores (according to population) in every large town and city, the stock issued by said association to be owned exclusively by the practising physicians of the town or city in which the drug-stores are located. The association to elect annually a board of managers, say of three or five of its members or stockholders, this board to appoint competent druggists to conduct the business of the several stores, the druggists to have no monetary interests whatever in the business, but to depend entirely upon their salaries—this will relieve them from any temptation to indulge in the art of substituting. These stores may carry a general line of druggists' sundries or do only a prescription business, as the association may elect.

I believe this plan will not only solve the vexed question, but will also yield a profit to the stockholders. Of course practical unanimity of action on the part of the physicians of each town or city is necessary for the success of the enterprise.

This plan will also put a stop to the universal habit of counter prescribing indulged in on the part of druggists, which is carried on to an extent beyond any idea conceived of by physicians generally.

Not one case in fifty of gonorrhœa is now treated by the physician, the druggists having completely captured that branch of the business which legitimately belongs to the physician. The same may be said in regard to many other diseases, and I have even known of their making a habit of treating syphilis.

Much more could be said in advocacy of the necessity of physicians associating themselves together for their mutual protection against their archenemy the druggist: but as this article is already longer than I intended, I will leave its further consideration to some other

CALIFORNIA, February 1, 1895.

ANTISEPTIC TREATMENT OF DIPHTHERIA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Discussion is the forceps for wisdom. So then, in answer to Dr. J. L. Proben: The mode of using the soft brush was described in my paper with the words: "which need be only a gentle touch—until complete disappearance of the membrane." This obviously meant without regard to situation. Trauma has, as a matter of fact, never been seen by me. The nose was in one instance, I remember, sterilized in the same manner with a smaller brush. For result in a pharyngeal case see the MEDICAL RECORD of February 25, 1893. That this simple, gentle treatment should yield such invariably good results may at first startle, but should not involve *a priori* condemnation.

CHARLES G. AMENDE, M.D.

266 WEST FORTY-SECOND STREET, NEW YORK.

MALARIA A WATER-BORNE DISEASE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the interest of getting at all the facts, the following questions ought to be answered in connection with, and as a part of, the report made by Dr. E. Kershner, Medical Inspector, United States Navy, etc., in the MEDICAL RECORD, January 5, 1895, viz.:

1. What were the exact dates during which the flagship New York laid respectively at St. Lucia, Rio de Janeiro, and Bahia? 2. What were the distances and locations from shore, and the geographical conditions of the nearest land? 3. What were the prevailing winds and other meteorological conditions? 4. What were the prevailing symptoms of the cases of malarial fever? 5. What were the means of diagnosis resorted to? 6. Were any specimens of blood inspected for the malarial parasite? 7. Are we to understand, literally, that "no one was permitted to go ashore at either of these places," as meaning that no officer, even of any rank, was permitted to, or did, go ashore at any of these places? 8. What, if any, sales, surreptitious or otherwise, were made to the men (including officers) by bumboats, of such drinks as pulque, or other possible native beverages, or milk, fruits, melon, or other vegetables, specifying them and their character? 9. What, if any, aërated waters were purchased and used there, naming brands, and where made?

W. H. DALY, M.D.

135 FIFTH AVENUE, PITTSBURG.

CIRCUMCISION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Referring to the controversy taking place in the recent issues of the MEDICAL RECORD, respecting circumcision, I would say that I am in perfect accord with the opinion of Dr. Levien: that the operation itself should be performed by the physician, or at least superintended by him. I have witnessed a number of these operations, and the want of asepsis or even ordinary cleanliness employed is sufficient to strike terror and apprehension to the physician of to-day, who is accustomed to the neatness and cleanliness of our operating-rooms in the hospitals and in private practice at the present time. That accidents and complications, which are preventable, do occur, and not infrequently, too—of that there is no doubt; these accidents being attended to and treated by the physician who is called in later, and thus the reports do not spread any farther,

or are prevented from reaching the public ear at all. Only recently I was hastily summoned to attend one of these cases; when I arrived, I found the child almost exsanguinated from the loss of blood. The operation had been performed about two hours ago, during which time the neighborhood was being searched for a doctor; the child bleeding profusely all this time. The underclothing and rags covering the penis were soaked with blood; the penis itself being covered with bits of rags, brown paper, solution of iron, etc., and presenting a most pitiable spectacle indeed. The hemorrhage was only controlled after passing a ligature around the penis proper, and the child slowly recovered from the severe shock and loss of blood it had sustained. Such and similar cases occur to almost every practitioner; then, why not have a physician present at the operation who can prevent or intelligently treat such accidents, should they arise, instead of hunting two hours or more for a doctor when they do occur. Certainly our system of the present day should be changed; the religious rite in itself should not be interfered with, but a physician ought to be present at every operation, and if he himself does not perform it, he should see that it is properly performed; that the patient is well cleansed; the genitals scrubbed and washed with bichloride or carbolic solution, the instruments sterilized, and above all the hands of the operator, not forgetting the finger-nails, clean and aseptic.

HUGO KUNZ, M.D.

101 EAST 105TH STREET.

New Instruments.

MODIFICATIONS IN THE OPHTHALMOMETER.

BY FRANK D. SKEEL, M.D.,

NEW YORK.

I WOULD like to call the attention of users of the ophthalmometer to a few minor improvements which I have made upon it in a way of increasing its general convenience.

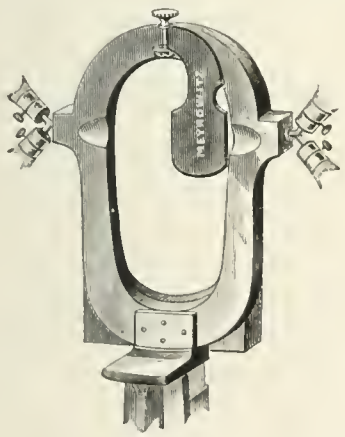

FIG. 1.—The Eye-Shade.

In place of the flap which was supposed to slide along a wire, but which seldom did so without some considerable persuasion, a shade is made of different shape and is hinged to the centre of the head-rest. It turns upon this hinge to the right or left as desired.

This device is to replace the mechanical monstrosity with which the instrument was originally provided, which required both hands and sometimes more for its proper adjustment. The rod which carries the chin-rest is made hollow and contains the pawl. The ratchet being inside the bracket through which the rod slides. By pressing a button which projects from the rod near its lower end, the pawl is disengaged and the rod may be raised or lowered to its proper place, where it will remain when the button is released. This can be done with one hand.

In adjusting the telescope so as to bring the centre of the corneal image on the cross wires, it has hitherto, been necessary to focus the instrument several times,

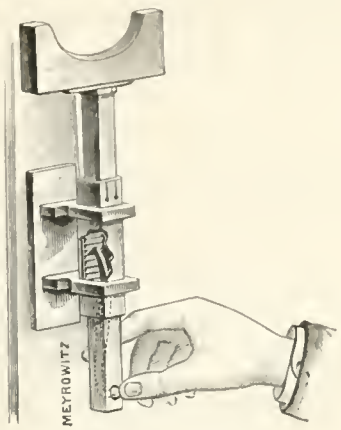

FIG. 2.—The Chin-Rest.

as the turning of the elevating screw instantly throws the image out of focus. The mechanism here described obviates this difficulty. The foot of the tripod base which carries the elevating screw, has a deep

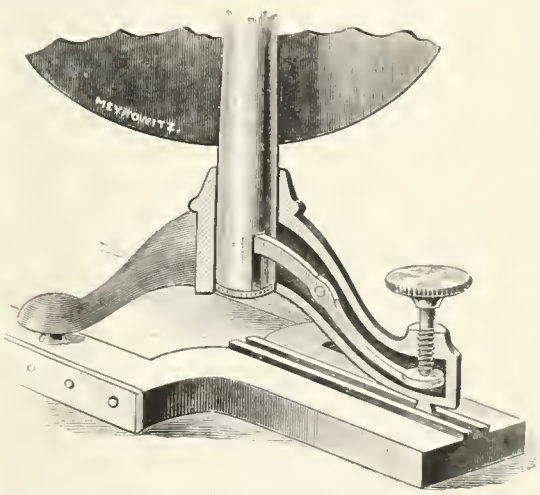

FIG. 3.—The Base.

channel in its under side to receive a lever. The short arm of the lever is acted upon by the screw, while its longer arm extends out under the central upright pillar, which is made to pass through the base. When the screw is turned downward, the pillar with its telescope is carried upward and *vice versa*, the pillar always remaining perpendicular. The focus being once found, is not lost while bringing the image of the mires to the centre of the telescopic field. The instrument as here described is made by Mr. E. B. Meyrowitz, of this city.

361 MOTT AVENUE.

Marion County (O.) Medical Society.—At the annual meeting of the Marion County Medical Society, held in Marion, the following officers were elected for the ensuing year: Dr. Dana O. Webb, *President*; Dr. D. S. Maddock, *Vice-President*; Dr. A. M. Crane, *Secretary*; Dr. H. L. Uhler, *Treasurer*; Drs. O. W. Weeks, W. C. Denman, and F. W. Thomas, *Standing Committee*. A new constitution and by-laws were adopted and signed by the members.

The Union Médicale.—With the beginning of the new year the *Union Médicale* has enlarged its size and transformed itself into a weekly, and has somewhat widened its scope.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 16, 1895.

	Cases.	Deaths.
Tuberculosis	93	136
Typhoid fever	3	8
Scarlet fever	97	16
Cerebro-spinal meningitis	3	2
Measles	79	4
Diphtheria	183	29
Small-pox	1	0

Removal of a Brain Tumor.—At a recent meeting of the Medical Society of London a paper by Dr. Beevor and Mr. Ballance, on "A Case of Subcortical Central Tumor Treated by Operation," was read and discussed. The patient, a woman aged thirty-nine years, had developed certain paralyses with diminution of tactile sensibility with affection of speech. The case was diagnosed as tumor, probably subcortical. Mr. Ballance operated in two stages at six days interval, first dissecting up a flap and removing a parallelogram of bone measuring two and a half by three and a half inches, and then (second step) incising the dura mater. The brain bulged, especially over the upper part of the ascending parietal convolution, and on this being broken through a growth presented itself. This was removed, leaving a cavity two inches deep in the brain. The optic neuritis, headache, etc., at once disappeared, and the patient soon regained tactile sensibility and the power of movement, except in the parts corresponding to the areas of brain removed. The authors held that such cases might be relieved either by total or partial removal of the tumor, by drainage of the tumor, or by incision of the dura mater and drainage. They had ascertained by experiment that mere removal of bone did not exercise much influence on intra-cranial pressure. In the discussion that followed, Dr. Taylor said that partial removal was justifiable, even when only relief of urgent symptoms could be expected. As to the effects of mere removal of bone on the pressure, he remarked that post-mortem examination of unoperated cases of cerebral tumor always afforded unmistakable evidence of pressure under the dura mater, the pressure being less intra-cranial than within the dura mater. Dr. Hale White said that in only about ten per cent. of cases was a radical operation possible, the tumor being too deeply seated, or multiple, or cerebellar. Among several cases of the kind he had met with, was one of a woman who developed a secondary sarcoma of the cortex after removal of the breast; it was remarkable that, though the symptoms pointed clearly to involvement of the arm centre, that area appeared to be quite healthy when exposed to view. He persuaded the surgeon to remove it, notwithstanding, and under the microscope it proved to be the seat of sarcomatous infiltration. So under certain circumstances it was not safe to rely upon the microscopical appearances. Their knowledge of cerebellar tumors was not yet such as to enable them to promise the same relief as followed drainage in cerebral tumors. He mentioned incidentally that such patients usually took the anæsthetic very badly. Dr. Mott asked how the authors accounted for the disappearance of the paralysis and the restoration of tactile sensibility after removal of so large a portion of the brain. Dr. Ormerod mentioned a case of a man who, after suffering from ordinary epilepsy, developed Jacksonian epilepsy with involvement of the arm centre. The brain was cut down upon, and a portion of a growth removed; immediate relief followed, but the man became insane and died, and at the autopsy a large tumor infiltrating down to the base was found. In closing the discussion, Mr. Ballance insisted on the advantages to the patient from even partial removal of such a tumor, and believed the same treatment was applicable to cerebellar as well as to cerebral tumors.

A Defect in Zoological Manuals.—At the meeting of the Association of American Anatomists in New York, Friday, December 28th, under the title "Loose Characterizations of Vertebrate Groups," Professor B. G. Wilder, of Cornell, reiterated a criticism already made in 1880, and in 1885, in his address as Vice-president of the Biological Section of the American Association for the Advancement of Science, viz.: Among characters that are alleged to distinguish groups from one another, some may really be constant and peculiar, but others are constant and not peculiar, others peculiar but not constant, and others neither peculiar nor constant. A marked instance of this confusion occurs in a recent English work. Besides tending to bewilder the student, and even mislead the naturalist, the speaker held that this ambiguity, in such marked contrast to mathematical and even linguistic treatises, prevented the recognition of natural science as a means of mental training and as a requirement for admission to colleges. As a remedy he urged that all Natural History courses embrace the principles and practice of logic, and that writers of manuals and text-books, while not neglecting correctness and completeness, pay more heed to the other commendable c's, clearness and consistency.

The Sleeping Sickness of West Africa.—This curious disease occurs oftener in males between twelve and twenty years of age, although all ages and both sexes may be affected with it. Enlargement of the cervical glands is seen at the onset; drowsiness and actual sleep at unusual hours are followed by profound and lethargic slumber lasting weeks or months. At first active purgation arouses the patient, but later he succumbs to the lethal slumber and refuses all food; emaciation with increasing atrophy, exhaustion, and starvation cause death at the end of from three to twelve months. When moribund, the coma ceases for a short time and the mental faculties are clear immediately before death. The most frequent and virulent cases occur in the valley of the Congo; others from the Congo to Senegal, in the Sierra Leone district, and in the Hinterland. Slaves taken from the Congo or Sierra Leone districts suffer from the disease when in the West Indies, etc. The prognosis is bad. Guérin reports 148 cases, all fatal. Gore says eighty per cent. are fatal. Forbes (*Lancet*) reports 11 fatal cases, also 2 which passed out of observation. At autopsy hyperæmia of the arachnoid and slight chronic pachy- and lepto-meningitis are found; the cerebral substance is pale, indicating anæmia of cortical centres. In one case splenic enlargement occurred, in 2 cases filaria sanguinis hominis were found, probably coincidences. The cause is unknown. Theories are: (1) septic condition of the blood, as suggested by the arrest of development of active glandular elements; (2) presence of filaria, as advocated by Mason; (3) a neurosis affecting the neurotrophic system, Forbes's suggestion. Treatment has proved useless.—*Boston Medical and Surgical Journal.*

The Clock was Non Compos.—A gentleman went to visit a friend who was an inmate of a lunatic asylum. When he had been there about half an hour he looked at the clock and asked if it was right. The lunatic gazed at him with a look of compassion for a minute or so, and then said: "Do you think it would be here if it *was* right, you lunatic?"—*Medical Press.*

A Monument to Dr. James Henry Bennet, the discoverer of Mentone, from a climatological point of view, was unveiled in that place on December 13, 1894.

MODERN SURGICAL TECHNIQUE.[1]

BY HENRY O. MARCY, A.M., M.D., LL.D.,

BOSTON, MASS.

BACTERIOLOGY has made possible a scientific basis for the formulation of the principles of wound treatment which has revolutionized modern surgery. It has clearly demonstrated the infectious nature of wound inflammation, the fundamental principles of which were first enunciated by Mr. Lister, in 1868.

The demonstration that fermentation, decomposition, and putrefaction were changes wrought by vital rather than chemical forces gave an entirely new phase to the subject of reparative processes in wounds. No chapter in the history of medicine equals in interest or importance the record of the scientific teachings which, step by step, have led to the present evolution of wound treatment. During a larger part of the entire period I have been a laboratory investigator, as well as surgeon, and have often thought that all that was needful in the way of practical teaching had been published, but new phases of the multiple subjects are constantly presenting, and it is of value to review and emphasize the factors of chief importance in operative surgery; since, in the wearisome maze of a seeming endless detail, the real principles may be lost sight of, and disaster follow instead of triumphant victory.

We now find the danger likely to arise from operative procedures not coming, as formerly, from those who do not believe stringent precautions necessary, but the rather from the complicated methods employed by the willing follower of modern teaching, who has but a superficial knowledge of surgical pathology. To be well equipped, the surgeon should have had a careful bacteriological training, since it is impossible to be guided by rules the true basic conception of which he does not understand.

The ritual of surgical technique must be learned in a painstaking manner, that it may become automatic in its application, as much as the speaking of correct English, since, as in speech, the mind should be dominated only by the central thought and not be distracted by detail. When this is true, the disinfected hand will not seek the pocket, the finger the ear or face, and the infected instrument or sponge will be discarded. He who is familiar with septic processes knows how easily infection from what seem the minor causes may occur; especially is this true in the lowered vitality of the cells and tissues of the body enfeebled by disease, when normally they possess a considerable inherent germicidal power. Thus the soil favors the reproduction of the deleterious product, while we all have learned the great variations in virulence which may pertain to the seed.

Experience teaches that several varieties of bacteria reproduce under favorable conditions in a way which seems, at the very onset, to overcome all inherent individual resistance. Hence the importance of a careful study of the various dangers which beset the patient and ever surround the surgeon. It is wise to admit that, by methods based upon present knowledge, we can never be certain that infection will not follow a given operation, and yet, under the present well-systematized régime, this is a very rare occurrence and should be rendered steadily less frequent.

Asepsis may be defined as the production of a condition where there is a complete absence of infectious material, the exclusion of all pathogenic organisms from the field of operation. To Dr. Welch and his assistants of the Johns Hopkins Hospital we are chiefly indebted for the demonstration that certain forms of pyogenic cocci have their normal habitat in the epidermal cells which are in process of exfoliation. It is probable that they serve a very useful purpose in aiding the human economy to rid itself of this worn-out material, but these infected epidermal cells are perhaps the most important of the foes with which the surgeon has to deal. On this account the greatest of all the dangers to the patient lies in the imperfect disinfection of the hands of the surgeon and his assistants, especially the deep parts of the skin beneath the finger-nail. The *contagium vivum* more often than from any, perhaps all other sources, consists in the transplantation of these loosened, infected, epithelial cells. Hence the importance of clean hands. Soap and water, well applied with a brush, will separate the larger share, but the maceration which necessarily goes on during a long operation will loosen many cells otherwise firmly attached, and surgical cleanliness means much more than ordinary washing. It implies a careful disinfection, and to Dr. Robb, of the Johns Hopkins Hospital, we are indebted for the demonstration of the practical sterilization of the hands by their immersion in a warm saturated solution of permanganate of potassium for two to five minutes, and then soaking them in a warm saturated solution of oxalic acid until the stain has completely disappeared. The oxalic-acid solution is, however, the chief disinfectant. The usual careful washing, soaking, and brushing of the hands in soap and water have, of course, been first practised. When the hands have been carefully disinfected, the accidental subsequent infection by contact is easily removed by washing in a mercuric solution of 1 to 1,000, since such material has a comparatively slight attachment to the surface.

Sponges.—Gauze has the advantage of being easily rendered sterile by steam-heating and is entirely trustworthy. This is, however, an imperfect substitute for marine sponges, which with care may be sterilized. After sponges are properly cleansed, they should be soaked in a 1 to 500 solution of mercuric bichloride for twenty-four hours, then carefully dried in a thin, sterilized muslin bag, in which they should remain until required. They should then be carefully washed in sterilized warm water and are ready for use. If they are ever contaminated by pus or septic material, it is better to throw them away. If used only in aseptic wounds, they are cleaned without difficulty and are trustworthy.

Drainage of Wounds.—In pus cases and septic wounds the drainage-tube becomes usually a necessary evil. In aseptic cases the rule should be not to employ drainage. At the best it is a confessed acknowledgment by the one using the drainage-tube that he lacks confidence in his ability to make and maintain a wound aseptic. It is ever, under all circumstances, an open door for the admission of a possible infection, and the later surgical writers so consider it. For years I have

[1] Read before the Mississippi Valley Medical Association, November, 1894.

scarcely drained in one per cent. of all major operations, laparotomies included.

Dr. Robb states: "Whereas a few years ago nearly ninety per cent. of all cases were drained, now we drain only from ten to fifteen per cent., and, indeed, from bacteriological investigations made in a large number of cases, it has been proved that, even under the most favorable conditions and with the personal attention of trained assistants, it is extremely difficult to prevent the access of pyogenic micro-organisms into the tube. We have pointed out that the presence of the white staphylococcus in the skin is a constant menace, where the way to a wound is kept open by a tube, and it was found that the dressing of the drainage cases led almost invariably, after two or three times, to bacterial contamination. Whereas we used to be afraid to close the abdominal wound completely, on account of the danger of sepsis, we now close it in every case possible, and rather hesitate from fear of infection to drain the wound." [1]

Hemorrhage.—In the control of hemorrhage the masters of a previous generation would consider that aseptic surgery had won one of its most brilliant victories. The necrotic processes necessarily supervening in septic wounds made secondary hemorrhage a frequent and dreaded danger. The aseptic ligaturing of vessels, as demonstrated by Mr. Lister, was one of the most valuable contributions ever made to surgery. The corollary to the proposition, the burying of aseptic animal sutures, was of equal importance. By this means hemorrhage can be controlled, and the wound closed layer by layer, leaving no pockets for the retention of fluids, and hence requiring no means for their removal. Thus the drainage-tube may be avoided and wounds securely closed and sealed from further infection. If a wound is aseptic, secondary hemorrhage can never occur. Operations that only a few years since were judged ill-advised at the best, or impossible on account of the fear of hemorrhage, are now done almost without danger.

Sutures.—All aseptic wounds should be carefully closed in a manner to coaptate easily the sundered tissues with the least possible injury to the parts. This is best accomplished by the use of buried continuous tendon sutures, applied so as to hold the parts at rest without constriction. Thus applied, the sutures may be used freely without fear. The stitches should, as far as possible, be taken deeply from side to side, and thus the suture crosses the wound at right angles only. It is surprising to note the amount of suture material which can be easily appropriated by the tissues, if it is aseptic and aseptically applied without undue constriction of the tissues in an aseptic wound. The skin should be closed by a line of running sutures, taken through the deeper layer of the skin, each stitch entering at a point exactly opposite the emergence of the former one. In this way the skin is coaptated without irregularity and its edges lie in exact approximation, without the appearance of the suture in any part of the wound. Thus buried in the deeper layer, it is beyond epithelial contamination. A layer of iodoform collodion, reinforced by a few fibres of cotton, completes the dressing.

For many years all my laparotomies have been conducted in the following manner:

The Patient.—The general condition has been carefully attended to previously. The site of the operative field is carefully shaven and disinfected, and the patient as far as possible is brought into the operating-room enveloped in disinfected clothing.

Operating-room.—The walls and floor are washed the night before the operation with a 1–1,000 solution of mercuric bichloride, and the room is closed. Every article in the room is similarly disinfected. For a long period I used atomization after its disinfecting power was shown to be comparatively unimportant. This I did that by the disseminated moisture all dust might be removed from the air of the surgery. A much simpler way to secure this, which I have since substituted and constantly use, is by the vigorous shaking by two persons of a sheet which has been wet in a strong mercuric solution. This may be seen to fill at once the air of the entire room with finely subdivided particles of water, which in settling take down all dust, so that the entering sunshine conveys no evidence of floating material.

Instruments.—Little need be said upon this subject, since all good operators sterilize their instruments, which is easily done by the use of moist heat. Not seldom does it happen that unnecessary attention to instruments has detracted from far more important considerations.

Instruments wrapped in a cloth wrung from a one per cent. solution of cooking soda (sodium carbonate) and placed in an Arnold steam sterilizer for five minutes, are disinfected without injury. All cotton or linen material used about the patient should be similarly disinfected.

Irrigation of such wounds as are possible is preferred to sponging, since the operative field is thereby kept constantly clean, and the tissues are injured less by a stream of sterilized water than by the contact of the sponge. I am by no means assured that injury results to the walls of the wound from weak mercuric solutions, and I continue to use them as the rule, having seen no serious consequences. In abdominal cases, where usually irrigation should not be practised, I have used for years oxygen gas. The gas is readily managed, as supplied in the small compressed cylinder. It is aseptic, and, rather for ease of judging of the volume escaping than for further purification, I pass the gas through a wash-bottle of carbolic-acid solution. The gas is conducted through a rather thick rubber tube directly over the operative field.

The advantage derived is chiefly in rendering the air about the field of operation aseptic. The gas is heavier than the atmosphere, and thus removes the surrounding air by displacement. The circumscribed atmosphere in a severe case is likely to become contaminated by the breath of the operator and his assistants, although the mouth of each has been carefully washed with a carbolic solution, a part of the preparation which should never be omitted. The chief objection to the use of gas is the complexity of further detail and expense. If, as some may think, of no use, it is surely harmless and not troublesome to manage.

I commenced many years ago, when we all attributed greater danger from atmospheric infection than at present, by using a special machine for conducting warm filtered air, in a constant current, upward from beneath the operating-table. This was serviceable, but required one attendant beside the occupying of room with a clumsy apparatus.

Then I arranged in the surgery a generating machine for the production of oxygen as a substitute. This, however, was uncertain of action and of some possible danger. Upon the easy securing of the highly compressed gas, I have used it, as above described, with the greatest satisfaction for several years.

At times it serves a valuable purpose, where for any reason the respiration is impaired. Twenty-five years ago Sir Spencer Wells taught me the importance to the patient of operating in a hot room. This led me to a careful study of the lowering of temperature, especially in abdominal operations, from the exposure of large surfaces—intestines, omentum, etc.—structures usually retained at a constant high temperature. About fifteen years ago, I constructed an apparatus for the conducting of water, at such temperature as seemed advisable, in a constantly changing current beneath the back of the patient when on the operating-table. This I used for some years, but it was expensive and required constant attention.

I adopted a simple substitute nearly ten years ago

[1] Aseptic Surgical Technique, 1894, p. 116.

which is in present constant use. In a false top to the operating-table is a recess which admits a flat tin tank, holding about three gallons, which is filled with water heated to about 110° F. A folded woollen blanket is placed over this, upon which the patient is laid. After an hour the temperature is plus 100°.

In a considerable variety of abdominal operations where the deep pelvic structures are involved, the adoption of the Trendelenberg position, patient reversed to a considerable angle, gives a natural advantage. Blind surgery is bad surgery, and by this simple measure the entire pelvic basin and its contents are safely under the inspection of the operator. In a very considerable number of laparotomies, I have derived marked advantage from this position. Unfortunately, I have had two deaths which I can attribute to no other cause, and both in young subjects, the autopsies showing no infection and no cause for the unfortunate result. I find upon investigation that several surgeons have had a similar experience. It behooves all of us, therefore, to use this new position with exceedingly great caution, and further investigation is required before we give it general adoption.

Scientific knowledge tends toward simplicity of detail. Emergency operations may be securely and safely conducted aseptically in the homes of even the very poor. The kitchen is usually the room to be selected ; first, it is generally the cleanest in the house, namely, freest from dust, has little furniture, few hangings, and usually painted walls. It has its independent heating apparatus and a water-supply. A few minutes suffice to give a clean warm room, free from dust, with plenty of hot water. If the operation must be done at once in a carpeted room with the modern limitless hangings, be sure not to permit sweeping, dusting, etc. The shaking of sheets, as referred to above, will give an atmosphere free from dust, and the spreading of these over the carpet after shaking will prevent the carpet from furnishing any further supply during the operation. The careful use of a large, inflated irrigating rubber receptacle will prevent any soiling of the floor.

The closing of the wound with buried sutures renders safe the sealing of it with a collodion dressing without drainage. This makes it possible to move patients without danger to considerable distances immediately after rather severe operations, if necessary, *e.g.*, a hernia case may be sent home in a carriage and suffer little or no risk.

Summary.—Recognize the infectious material as if it were a visible, palpable element. Based upon such knowledge, enter upon an intelligent sterilization of patient, materials used, instruments, assistants, and by far the most important of all, the operating hands. Having made an aseptic operation, close the wound with buried tendon sutures and seal without drainage. This having been effected, the wound is safe, and the labor, care, and anxiety attendant upon all our earlier operative procedures for the ensuing weeks are entirely obviated. The work is ended when the patient leaves the operating-room. Once mastered, the technique is really easy.

Science has not alone shown the safe and sure way toward recovery, but, as is usually the case, the really, in the end, easy path to pursue. Let the coming century find no practising surgeon who is not master of his surgical technique, as the high priest of a most sacred calling.

Almost unconsciously we are led to think of modern surgical technique as an *art* rather than a *science*. Let us so accept it. Based upon scientific principles, the work should be artistic ; a blundering surgeon may be aseptic, but this should never be an excuse for clumsiness. The true surgeon is skilful, which term means so much, full of that skill which makes his work really correctly automatic ; like the master of a musical instrument, who through it pours forth the enraptured strains of soul-inspiring, moving power, with never the thought of hand or bow or string.

Anæsthesia and asepsis have brought into surgery a small army of men who lack the training which, half a century ago, was considered absolutely essential to success. Then to be a surgeon meant an apprenticeship. Should it be less at the present time ? The greatest danger to-day lies in the willing, enthusiastic, but half-trained recruits with which our ranks are overcrowded. Here as elsewhere comes the law of the survival of the fittest, but at what fearful cost of life, matched, almost overshadowed, by the self-condemnation which permits of no condonement !

The recent address on surgery before the British Medical Association, by Mr. J. Grieg Smith, " The Art of the Surgeon," should be read by every student, by every surgeon. " That the art of surgery is teachable there can be no dispute ; that it is worth teaching is still less disputable. Why, then, is it not taught ? The art can be taught only in one way, the way of teaching all the plastic arts. The young artist must, while beginning the practice of his art, have a master at his elbow, a master who will guide him in the use of his hand, his eye, and his instruments ; who will in the fullest sense make him his pupil and personally lead him on, step by step, toward such excellence in the art as he himself has attained. . . . We might ask to be put on the level with the fine arts, and seek for a Royal Academy of Surgery, as we have Royal Academies of Painting, Sculpture, and Music. To such an academy a school of teachers should be attached. The school would be a surgical hospital with every known excellence of hygiene and nursing and appliance. The teachers would be those who are superior in our art, the pupils men who are already qualified, who seek for practice in the higher walks of surgery ! Then let us work for it."

A great art is not builded in a day. We profit from the experience of our predecessors. The coming generation will have much to criticise in the review of our labors. Let them also find themselves indebted to us for much experience of real value in both the science and the art of surgery.

THE TREATMENT OF PULMONARY TUBERCULOSIS WITH CINNAMIC ACID.[1]

By ALEXIS V. MOSCHCOWITZ, M.D.,

NEW YORK.

As indicated in the title of this article, it is not my intention to dwell upon the etiology, diagnosis, and pathology of pulmonary tuberculosis. I desire to discuss merely one more recent method of treatment : that proposed by Professor Landerer, of Leipzig, in the year 1891, and which has been in use since that time with but slight modifications and with really remarkably good results.

The favorable results Professor Landerer has published from time to time, and particularly the satisfactory reparative alterations in the diseased lung-tissue which appear to have been attained by this mode of treatment, induced me to give it a trial. Experiments were commenced during my service on the staff of the German Hospital. Afterward lack of material, as well as want of time, prevented me from continuing them. It is only since the end of the year 1893 that I have again been enabled to take up these observations.

I am quite well aware of the fact, that it is impossible to form a conclusive opinion after so short a period of observation, particularly in the case of so obdurate and treacherous a disease as chronic pulmonary tuberculosis.

If I publish my results now it is because, though not as good as those obtained by Landerer, they are still

[1] Read at the meeting of the German Medical Society of New York, December 3, 1894.]

sufficiently encouraging, and I have deemed it my duty to call more general attention to a method of treatment which seems to merit extended trial by the medical profession.

The treatment consists of intravenous injections of cinnamic acid. Cinnamic acid can be prepared from gum benzoin, styrax, or Peruvian balsam. As proposed by Landerer, I use only a cinnamic acid which is made out of storax, and which should have the following physical properties: it is an absolutely colorless and odorless, coarsely crystalline powder, very slightly soluble in cold water; soluble in boiling water, alcohol, and fatty oils; the resulting solutions should be absolutely colorless. A cinnamic acid which does not correspond with above physical properties should be rejected.

The cinnamic acid is used in the form of an emulsion, the formula of which is as follows:

℞. Acidi cinnamylici subtiliter pulverisati. .	5.0
Olei amygdalarum.	10.0
Vitelli ovi.	No. 1.
Solutio natrii chlorati (0.7 per cent.).	9.5.
Ut fiat emulsio.	100.0

To avoid all mistakes, I deem it best to translate literally the original directions regarding its preparation. "Absolute accuracy is a first requisite in a proper preparation of the emulsion. The cinnamic acid is to be rubbed into a fine powder in a mortar, then the powder is intimately mixed in the mortar with a portion of the oil, whereupon the balance of the oil is added; then the yolk of the egg, after being freed from the chalazion, is added to the mixture; after all these have been properly mixed together, the 0.7 per cent. solution of NaCl is added, drop by drop, slowly, and in portions, constantly stirring, until the weight of 100.0 is reached." It is self-understood that all utensils must be previously sterilized.

The emulsion, prepared according to these directions, is in the form of a milky fluid, the color of which, depending upon the color of the yolk of egg used, varies from almost white to light lemon-yellow; its reaction is strongly acid; even after standing quietly for a number of days its consistency should be uniform, and should show neither a deposit of cinnamic-acid crystals, nor should a creamy layer form on the surface. The emulsion keeps well even for a number of weeks, especially if preserved in a cool place. I have used an emulsion four or five weeks old without producing disturbances.

The one thing to be regretted, as may be readily inferred from its composition, is that the emulsion itself cannot be sterilized; but this is not a very great drawback, as a properly prepared emulsion will be sterile even after some weeks' standing.

Before using the emulsion it must first be rendered alkaline. For this purpose a twenty-five per cent. solution of chemically pure caustic soda is used, which should be added repeatedly, as the alkalization takes place but very slowly. To render 2.0 of the acid emulsion alkaline, about five drops of the NaOH solution are required. It is important that the emulsion shall be thoroughly alkaline for the following reasons: The acid emulsion, when examined microscopically, will be found to consist of minute fat droplets, between which the minute cinnamic-acid crystals are in suspension, which latter disappear only after the emulsion has been rendered alkaline; furthermore, an insufficiently alkaline emulsion may cause distressing disturbances.

The following is the apparatus required for a treatment: 1. The emulsion. 2. Twenty-five per cent. solution of chemically pure caustic soda. 3. A good hypodermic syringe, which should not be used for any other purpose. I use an ordinary hypodermic syringe, which I cleanse from time to time with alcohol, and which is always kept in a two per cent. solution of carbolic acid. 4. A few very sharp hypodermic needles, of a rather large calibre. 5. A physiological solution of NaCl (0.7 per cent.). 6. Solution of bichloride of mercury, 1 to 1,000. 7. Iodoform-ether. 8. A short Martin's bandage. 9. Cotton, gauze, bandages, etc.

The technique of the injection proper is as follows: First of all, it is necessary to sterilize by boiling the hypodermic needles and a small vial or dish, in which the emulsion is to be rendered alkaline; now the emulsion is made alkaline, and its reaction again tested with red litmus paper. The syringe is then prepared by aspirating through it repeatedly some normal salt-solution. The patient takes his seat in a proper and convenient position, when the elastic bandage is applied to the upper arm, not too tightly (almost as if for a venesection).

The anterior aspect of the elbow-joint or the region of the vena cephalica is then cleansed thoroughly, first by scrubbing it with bichloride of mercury solution, and afterward washing it with iodoform ether; by this latter manipulation the veins are made very prominent.

After filling the syringe with the required dose, taking care to remove all air-bubbles, it is held parallel to the vein into which we intend to inject; the needle is inserted into the vein through the skin, under a very acute angle, and the contents of the syringe evacuated with but very little pressure.

Just here there is a point which I would like to emphasize, *i.e.*, before evacuating the contents of the syringe, it is necessary to be certain that the needle is well within the vein and is not lodged in one of the coats of the vessel or in the subcutaneous connective tissue. If the needle is in the lumen of the vein, we can feel at once that it moves in a hollow space, and the injected emulsion disappears at once without leaving any trace. If the injection is followed by a slight elevation, it shows that the needle is not within the vein; should this happen, it is best to withdraw the syringe, and to reinsert it at some other point.

A small piece of gauze is placed upon the seat of injection and is fastened by a few turns of a bandage; this bandage may be removed in an hour or two. After the injection the rubber bandage is loosened, and the entire manipulation is completed.

An injection properly executed is painless; occasionally a patient complains of a slight burning sensation, which lasts for a few minutes; an injection improperly executed, however, especially if a part of the emulsion has been injected into the subcutaneous connective tissue, is, as I have had occasion to find out, exceedingly painful; but is not followed by any further untoward symptoms, and may, in a great measure, be alleviated by a Priessnitz's dressing.

In general it may be said that a properly performed injection, provided that an appropriate dosage has been selected, is not followed by any immediately noticeable reaction. Once only did it happen in my own personal observation (in Case V.) that the first injection was followed by dizziness, oppression, nausea, and later on also an involuntary evacuation from the bowels.

It is self-understood that where, as in this method, a substance is introduced directly into the circulation, even such simple manipulations as have just been described may be followed by phlebitis, or other more serious septic infections, unless the most accurate and most painstaking asepsis and antisepsis are observed. It is safe to say, where such unpleasant complications happen, the fault lies always with the operator.

The dosage of each injection is adjusted to the general condition of the patient. In general it may be said that weak and exhausted patients can stand only very small doses. I usually commence with five drops of the emulsion, and rise gradually with half a drop at each injection, until twelve drops are reached, with which amount I continue.

As a rule I allow two days to intervene between each injection; if the patient is very weak, it is preferable to inject every alternate day, but then only very minute doses (five to six drops) are permissible.

Regarding the duration of the treatment, I am not in

position to give a definite opinion from my own personal observation; according to Landerer, the treatment should be continued at least four weeks after the disappearance of tubercle bacilli from the sputum.

Theory of this Method of Treatment.—Cinnamic acid, as well as its salts, as I have been repeatedly able to demonstrate on myself, my patients, and on rabbits, are positively chemoctatic; that is, they have the power when injected into the circulation to produce an increased leucocytosis. This increase in the number of the white blood-cells is noticeable a short while after an injection, and reaches its height about eight hours afterward.

Landerer has investigated, and published in a monograph on the subject, the subsequent process of healing of pulmonary tuberculosis, under the treatment with cinnamic acid. P. Richter corroborated this, and published his highly interesting results in *Virchow's Archiv*, vol. cxxxiii., as follows:

Richter infected nine rabbits by injections with fresh cultures of tubercle bacilli. Three of the animals died within nineteen days, of which two died from distinct general tuberculosis. The remaining six were then treated for six months with cinnamic-acid injections; all of them gained in weight; were then killed at various intervals, and the tubercular organs examined microscopically. His results enable him to divide the process of repair into four stages:

1. The stage of leucocytosis; an aseptic inflammation develops around the tubercular deposits, just as we find it everywhere, as a result of any chemical, mechanical, or thermic irritation; that is, we get a dilatation of the smaller arterioles, an exudation of serum, and an emigration of white blood-cells.

2. The stage of circumvallation, which is noticeable already in the third week; about this time there forms a thick zone of white blood-cells around the tubercular deposit, which shuts it off from the surrounding tissues; at the same time, there begins also an immigration of leucocytes into the tubercle itself; a new formation of blood-vessels is also noticeable.

3. The stage of vascularization; new connective tissue takes the place of the pre-existing zone of leucocytes; from which also new connective tissue and new blood-vessels grow into the tubercular deposits. Tubercle bacilli should have disappeared by this time.

4. The stage of cicatrization and shrinkage; the formerly mentioned new connective tissue is transformed into cicatricial tissue; that is, in place of the tubercular tissue we get a solid and lasting cicatrix.

Cinnamic acid has no effect whatever upon the tubercular deposit itself; the result may be principally attributed to its action upon the surrounding tissues, because it has the power to induce here an aseptic inflammation, which leads to an encapsulation of the tubercle; to a cessation of tissue changes in its interior, and so produces a disappearance and death of the tubercle bacilli.

I have treated until now, by this method, eleven patients; but notwithstanding an exact observance of Landerer's directions, my results are not correspondingly good. According to the statistics which he publishes in the *Therapeutische Monatshefte* (February, 1894), he divides all the cases of pulmonary tuberculosis, with respect to prognosis, into four different groups:

a. Cases of chronic pulmonary tuberculosis, with fairly preserved general nutrition, give an almost absolutely good prognosis and terminate in recovery.

b. Cases with demonstrable cavities, but no fever, give, according to these statistics an improvement in 66⅔ per cent. of the cases.

c. Cases with demonstrable cavities and high temperatures give a bad prognosis; although a subjective amelioration of the symptoms is induced by the treatment.

d. Cases of so-called "galloping consumption" give an absolutely bad prognosis.

If we now observe critically the eleven cases which I have treated, we find that, perhaps with the exception of Case X., not one with whom I would be justified to give a fair prognosis; of the rest nine cases belong to the second group, and one, Case IX., to the third group.

Two of the cases died. In the first, Case IX., the prognosis was absolutely bad from the very start; in the second, Case IV., material improvement followed the treatment, and I felt justified in my view that the case would eventually be cured, but it terminated fatally, through an intercurrent catarrhal pneumonia.

Six of the cases, I., III., V., VI., X., and XI., all showed material improvement. The remaining three cases, II., VII., and VIII., admit no opinion. The duration of the treatment was too brief, as they received only ten, six, and five injections respectively.

Drawbacks of this method of treatment are the minute and certainly circumstantial preparation of the emulsion, and the uncertainty of intravenous injections in general. To obviate these Landerer suggested the use of a five per cent. solution of cinnamate of soda; but its use has not stood the test, neither intravenously nor subcutaneously. Nor have intramuscular injections in the gluteal region, which have been tried by Landerer, been particularly successful, as he states in a personal letter to me in January of this year.

Landerer uses this method, not only in the treatment of pulmonary tuberculosis, but also in the treatment of tuberculosis of other organs; as in the tuberculosis of joints, glands, peritoneum, larynx, lupus, etc. Wherever they can be reached, the cases are not only injected but treated also locally with applications of either a ten per cent. alcoholic solution or suspension in glycerin. In these cases the results seem to be even better than in pulmonary tuberculosis.

Before closing I take the liberty to state that with these facts I lay claim to neither originality nor to brilliant results; nevertheless the results of this method are sufficient to stimulate to further trials.

Following are condensed histories of the eleven patients treated by me. In their perusal, I would call attention of the fact that none of these patients received any internal medication with creosote, guaicol, or allied drugs.

Case I.—S. K——, thirty-two years of age, journalist. Anamnesis: the father of the patient died of pulmonary phthisis. Patient complains since about a year of a very distressing cough, but up to two months he was still able to follow his occupation; since that time the cough is decidedly worse; anorexia, night-sweats, dyspnœa and diarrhœa, as well as a complete breaking down set in; so that he was obliged to be confined to his bed. During the past year the patient lost about twenty-five pounds in weight.

Status præsens on October 10, 1893: Poorly nourished, very anæmic man. Pulse rapid (120); temperature, 104° F. Retraction of the right fossa supraclavicularis; relative dulness over both apices, behind as well as in front, especially, however, on the right side, where the dulness extends down to the fourth intercostal space; here also numerous large and small râles are to be heard; expiration prolonged; bronchophony and bronchial breathing. Furthermore also on the left side complete dulness, which extends up to about one inch above the inferior angle of the scapula; over this part there is also absence of voice, breathing, and vocal fremitus. Numerous tubercle bacilli in the sputum, as well as in the subsequently removed (750.0) sero-sanguineous fluid from the left pleural cavity. Diagnosis: tuberculosis of both apices; tubercular pleurisy of the left side.

Before commencing the treatment the patient consulted a very prominent colleague regarding the advisability of removal to a more suitable climate; his condition, however, was so poor, and the prognosis so bad, that such a course was not to be considered. He re-

mained, consequently, in the city and received, from October 30, 1893, to January 1, 1894, fourteen injections. On December 14th already his condition was so much improved, that, notwithstanding my advice to the contrary, he returned to his occupation. During this time he gained eight pounds in weight; his appetite improved; repeated examinations allowed me to presume a cessation of the process. The number of the tubercle bacilli grew gradually less, so that toward the end I could find only with difficulty a few isolated ones, and even these only with difficulty stainable.

The patient discontinued the treatment on January 1, 1894, and has since followed his occupation, daily from 4 P.M. to 2 A.M.; furthermore, according to his statement, in very poorly ventilated rooms.

On my invitation the patient again called upon me on July 13, 1894. Examination on that date showed him to be fairly well nourished (he gained namely further five pounds). Retraction of both apices; slight dulness, especially on the right side; respiration weak; no râles. Patient, however, is coughing again, and the number of tubercle bacilli has also increased. I advised the patient to recommence the injections; as his time is, however, fully occupied and being naturally careless, he received only eight injections at very irregular intervals. Improvement again followed the injections, but the patient is so irregular in attendance that very much cannot be expected.

CASE II.—J. G——, twenty-five years of age; printer. Anamnesis. Family history is good. Patient perfectly well up to six weeks ago; complains since that time about general weakness, pain in the back and extremities; on alternating days there are chills, followed by high temperatures. A course of treatment with quinine causes these symptoms to disappear. The patient, however, did not feel better and began to complain of a slight cough, which was soon followed by night-sweats.

Status præsens on September 2, 1893: Fairly well nourished young man; the spleen is enlarged; very slight relative dulness over the right apex; no râles.

On October 5th and 6th the patient had two quite severe hemorrhages; after being able to demonstrate a few tubercle bacilli in the scanty sputum, I commenced with the injections, of which the patient received ten from November 8th to December 7th. The night-sweats disappeared, and the general condition also improved markedly, with a gain of three pounds in weight, when the patient left the city and, much to my regret, also the treatment.

CASE III.—B. H——, twenty-one years of age; seamstress. Anamnesis. A sister of patient died of pulmonary phthisis. Patient born in Roumania; was very sickly in her childhood; is a resident of the United States since eight years, and, probably as a result of sufficient and better nourishment, gained so much in weight that a year ago she weighed one hundred and sixty pounds. Complains since two years of a cough and of pain and oppression in the chest, especially behind the sternum; rapid loss of flesh and strength; had numerous small and one rather severe hemorrhage. Was operated upon one year ago in the Mt. Sinai Hospital for a tubercular fistula in ano.

Status præsens on December 24, 1893: Fairly well nourished woman, notwithstanding the alleged loss of weight. Slight dulness over the left apex; on the right side the dulness extends posteriorly as far as the inferior angle of the scapula, anteriorly to the third rib. Respiration diminished and superficial; forced inspirations give rise immediately to a violent attack of coughing; sibilant and sonorous breathing and a multitude of coarse and fine râles; appetite poor; sleep disturbed by night-sweats. Sputum contains a very large number of tubercle bacilli.

The veins of this patient were so poorly developed, that even with a Martin's bandage I could hardly make them sufficiently prominent for a successful injection; consequently I was obliged to be satisfied with intramuscular injections in the gluteal regions. Patient received in consequence from December 24, 1893, to April 8, 1894, six intravenous and twenty-five intramuscular injections.

During this time the patient showed a gain in weight of only one pound; the dulness over the left apex has disappeared almost entirely; on the right side, however, the improvement was but very slight. In the summer of this year the patient was sent to the country by a charitable organization and I saw her but once since, shortly before her return to Roumania, on which occasion I could certainly recognize a distinct improvement.

CASE IV.—F. B——, thirty-nine years of age; butcher. Anamnesis. Family history is negative; gives a moderate history of alcoholism; his previous history has but very little bearing upon his present trouble up to February, 1892, at which time he had an attack of pneumonia; although he recovered, he was still so weak that to recuperate his health he went to Europe for five months and returned apparently entirely recovered. In March, 1893, he returned to his occupation, but soon began to fail again, so that in October of the same year he was again obliged to retire from business. During this time the patient had a number of pulmonary hemorrhages. Since then he complains of a very distressing cough and of pain and oppression behind the sternum; about this time aphonia also set in.

Status præsens on January 25, 1894: Extremely emaciated man. Retraction of both apices; slight dulness in front over the left supraclavicular fossa; on the right side anteriorly there is flatness, which extends down to the fourth intercostal space; posteriorly dulness over the left fossa supraspinata; on the right side again flatness, extending down to the inferior angle of the scapula; below this there is a zone about two inches in breadth where there is normal pulmonary resonance, and below this again dulness. Auscultation reveals sharpened respiration and prolonged expiration over the left apex; on the right side, over the consolidated portions, there was bronchophony, bronchial breathing, and a multitude of fine and coarse râles. Appetite poor. Sleep very bad on account of night-sweats. Body weight, 120 pounds, although one year ago it was still 178 pounds. Sputum almost a pure culture of tubercle bacilli.

On January 25, 1894, I commenced with the injections; after the third injection the patient noticed an improvement so far that he could sleep better, not being disturbed by night-sweats.

From January 25th to May 28th, including an interval of three weeks in April, the patient received twenty-six injections; during this period he improved markedly in every respect; the dulness over the left apex has disappeared almost entirely; on the right side there was dulness over the apex only, but no râles were to be heard; tubercle bacilli in the sputum were so few that I could find them only with the greatest difficulty; the aphonia has disappeared entirely.

At the injection of May 28th, evidently an error crept in in the usual asepsis, as a slight localized phlebitis set in, which obliged me to suspend the injections temporarily.

From July 1st to the 14th, the patient again received five injections; at this time, that is, after five months of treatment (including several pauses) and after thirty-one injections, I sent the patient to the country in a really remarkably good condition; much to my regret he returned within two weeks with a general catarrhal pneumonia, which ended fatally on September 7th.

CASE V.—Mr. J. W——, thirty-five years of age; furniture packer. Anamnesis. One brother and one sister died of pulmonary phthisis; history of an excessive use of alcohol. About a year ago patient had a very severe attack of influenza; since that time he complains of a cough, the accompanying sputum being occasionally bloody; appetite poor; night-sweats; loss of fifty

to sixty pounds in weight during the past six months; loss of strength, so that he was obliged to give up his occupation.

Status præsens on February 2, 1894: Poorly nourished man; color cyanotic; dulness of both apices, especially on the right side, where the dulness extends anteriorly to the third rib, and posteriorly to about one inch below the spine of the scapula. Respiration superficial; coarse and fine râles to be heard on both sides. Numerous tubercle bacilli in the sputum.

Patient received the first injection on February 2d, and as subsequent events showed, I commenced erroneously at once with eight drops of the emulsion; about five minutes after the injection the patient became very pale, and complained of dizziness, so that he fell off the chair; this was followed by an extremely violent attack of coughing and vomiting, and an involuntary passage from the bowels; patient was so weak that he was obliged to remain in my office for over an hour.

On February 6th patient received an injection of eight drops, but intramuscularly in the gluteal region.

On February 12th I again ventured to make an intravenous injection of five drops; this was also followed by an attack of coughing, and I feared a repetition of the symptoms of the first injection; but fortunately it stopped with the coughing.

Since February 2d the patient received nineteen injections, including two in the gluteal region. On April 26th he was sufficiently recovered to return to his laborious occupation (it is self-understood contrary to my advice) and has not again returned for treatment. An examination shortly before that date revealed almost the same physical signs as the first examination, with the exception of the fact that no râles were to be heard, and that the tubercle bacilli were only very few in number and with difficulty stainable. Gain in weight, nine pounds.

Case VI.—Henry V——, forty-one years of age; beer-bottler. Anamnesis. Family history unknown. Patient complains since last August of a cough and irritation of the throat; expectoration scanty; slight loss of flesh and strength.

Status præsens on March 2, 1894: Tuberculosis of the larynx, kindly treated by Dr. Ledermann at the Mt. Sinai Dispensary, at first with lactic acid, later with a ten per cent. alcoholic solution of cinnamic acid. Fairly nourished man. Dulness of the right fossa supraspinata; expiration prolonged; bronchophony and bronchial breathing; occasionally also râles to be heard. Dyspnœa and dysphagia as a result of the laryngeal tuberculosis. In the sputum tubercle bacilli.

Patient received from March 20th to May 6th twenty injections; during this time there was a gain in weight of twenty pounds; subjective and physical improvement also set in; dulness over right apex barely noticeable; no râles to be heard; number of tubercle bacilli decidedly diminished.

Case VII.—A. G——, thirty-two years of age; violinist. Anamnesis. Family history unknown. When twelve years of age patient had an attack of Asiatic cholera. On September 9th of last year he was operated upon at the Mt. Sinai Hospital for a tubercular lymphadenitis of the neck. Complains since about a year of a very distressing cough; last winter a number of hemorrhages; slight loss of weight.

Status præsens on March 8, 1894: Fairly well nourished man. A small abscess is visible in the cicatrix on the right side of the neck. Dulness anteriorly as well as posteriorly over the right apex; expiration prolonged; a few moist râles as well as pleuritic friction sounds are to be heard; the voice is hoarse, but with the exception of a chronic pharyngitis there is nothing abnormal in the throat.

Patient received from March 14th to March 30th (at which time he left the city) six injections; during this time there was a gain of four pounds in weight; the physical signs were the same as at the first injection, but no râles were to be heard.

Case VIII.—J. J. P——, twenty-nine years of age; carpenter. Anamnesis. An aunt of patient died of pulmonary phthisis. History of the abuse of alcoholic stimulants and cigarettes. Previous health good up to two years ago, since which time he complains of a cough, at first dry, later with abundant expectoration, occasionally mixed with blood; since last October a loss of fifteen pounds in weight.

Status præsens on March 12, 1894: Poorly nourished, very anæmic man. Dulness over both fossæ supraspinatæ and fossæ supraclaviculares, especially on the right side. Respiration sharpened; râles to be heard on deep inspiration; numerous tubercle bacilli in the sputum.

Patient received from March 14th to 27th five injections; during this time there was a decided improvement in the general condition of the patient, but with the exception of a diminution in the number of the tubercle bacilli no physical improvement was noticeable.

Case IX.—M. G——, twenty-four years of age; housewife. Anamnesis. A sister of patient is now suffering from pulmonary phthisis; another sister has a lupus of the nose. One year ago patient had an attack of pleurisy on the left side; since that time she complains of a cough, at first dry, later with abundant expectoration; never any hemorrhages; no night-sweats; anorexia; great loss of weight; since four weeks obliged to stay in bed.

Status præsens on July 6, 1894: Extremely emaciated, very anæmic woman. Marked retraction of both apices, especially on the right side; dulness over both apices extending anteriorly down to the fourth intercostal space and posteriorly to the spine of the scapula. Respiration superficial on the left side; on the right side bronchophony and bronchial breathing, and numerous coarse and fine râles; dyspnœa. Rise of temperature every evening up to 105° F.; sputum almost a pure culture of tubercle bacilli.

Patient received from July 6th to August 13th eleven injections; at no time was there even the slightest improvement noticeable, with the exception of the fact that the evening temperatures did not rise quite as high.

The prognosis in this case was from the very start so bad, that only with the greatest reluctance could I be prevailed upon to give the patient the benefit of the doubt and to commence with the injections; during the course of the treatment, also, I was several times on the point of discontinuing them, but the patient flattered herself that she felt better after each injection; I was, therefore, morally compelled to continue them until exitus lætalis occurred on August 15th.

Case X.—H. H——, thirty-two years of age; druggist. Anamnesis. Family history good; previous health always very good. Patient first complained of night-sweats in the middle of the winter 1893 to 1894. Patient, an intelligent man, dates his trouble exactly from April 25, 1894, at which time he commenced to complain of a dull pain and a peculiar oppression along the sternum and in the larynx; coughs since about a month; never any large hemorrhages, but the sputum was frequently streaked with blood. Loss of seventeen pounds in weight during the past two months.

In this anamnesis I would call especial attention to the fact that I was able in this case to trace exactly the source of infection. Patient, previously perfectly healthy, married a year and a half ago a young Spanish woman (whom I later also had occasion to examine), in whose family several near relatives died of pulmonary phthisis and who is herself decidedly phthisical.

Status præsens on July 22, 1894: Fairly well nour-

ished man, notwithstanding the alleged loss of seventeen pounds in weight. Retraction of the right apex; anteriorly over this portion of the lung the percussion is of fair quality, but the pitch is somewhat higher and the duration shorter; posteriorly there is dulness; the breathing is tubular; on deep inspiration a few râles are also to be heard; swelling of the right arytenoid cartilage; a small ulcer is visible on the right half of the free border of the epiglottis. In the sputum tubercle bacilli.

Patient received from July 14th to August 18th twelve injections; furthermore I also painted the larynx with a ten per cent. alcoholic solution of cinnamic acid. The tubercle bacilli have disappeared entirely, and the ulcer on the epiglottis has healed. During the twenty-five days of actual treatment there was also a gain of fifteen pounds in weight.

On August 20th the patient left the city for Mexico; occasional letters from him bring me the news of continued good health.

Case XI.—V. M——, twenty-six years of age; waiter. Anamnesis. Family history is negative. In the winter of 1892 to 1893 patient had a number of pulmonary hemorrhages, and again in July, 1893, and in February, 1894; after this his health was fair up to July of this year, at which time he again had a number of small hemorrhages. Complains of pain in the left side of the chest, dyspnœa, and cough; since some time also night-sweats. Loss of weight, ten pounds.

Status præsens July 22, 1894: Fairly nourished man; color cyanotic. Retraction of the left apex; dulness anteriorly as well as posteriorly, especially the latter. Respiration shallow, soft, and blowing; on deep inspiration a few râles are to be heard. In the sputum tubercle bacilli.

Patient received from July 24th to September 10th sixteen injections; during this time the general condition of the patient improved so much that he could undertake quite laborious work. Gain of ten pounds in weight. Patient discontinued the treatment on September 10th, and felt very good; his physical signs also improved so much that a colleague who examined him about that time could barely tell which portion of the lungs was affected. I regret to state, however, that I received lately the news that he again had some hemorrhages, but he refuses treatment.

364 West Fifty-fifth Street.

VAGINAL CŒLIOTOMY.

With Remarks on the New Field it Opens up for the Treatment of Backward Displacements of the Uterus with Diseased Annexa by Vagino-fixation.

By HIRAM N. VINEBERG, M.D.,

Instructor in Gynecology in the New York Post-Graduate Medical School and Hospital; Attending Gynecologist to Mount Sinai Hospital Dispensary, and to the Montefiore Home for Chronic Invalids.

In a recent paper[1] on the indications of vagino-fixation, I stated that when one or both annexa were diseased, calling for removal, cœliotomy and ventro-fixation, rather than vagino-fixation, would be indicated. Some recent experiences have shown me that I drew the lines of indication entirely too narrow, and that the field of the operation may include the majority of backward displacements with adhesions and diseased annexa. The operation, therefore, is likely not only to supplant Alexander's operation, but to take the place of abdominal cœliotomy and ventro-fixation in a great number of cases. When I first began doing vagino-fixation, over fifteen months ago, I was struck with the ease with which I could, in the majority of cases, deliver the fundus of the uterus through the vaginal wound. I was thus enabled to pass the uterine sutures with the aid of sight, and to pass them as near the fundus as I desired. Judging from the description of the operation by Mackenrodt, Dürrsen, and Winter, this was not an unimportant modification. These operators did not bring the fundus out through the vaginal wound, but passed the uterine sutures with the uterus in the vesico-uterine space, and consequently were compelled to rely chiefly on the sense of touch. While performing the operation it frequently occurred to me that I could easily tear through the fold of peritoneum between the bladder and uterus (as I had frequently done without intention), and draw one or both annexa out through the vaginal wound if I so wished. But as I had operated only in cases in which the annexa were apparently healthy or slightly diseased, I did not care to submit my patients to any extra risk by attempting an unnecessary manipulation within the peritoneal cavity. However, since the agitation of the past few months in favor of selecting the vaginal rather than the abdominal route for work in the lower part of the peritoneal cavity, I determined to put to the test the feasibility of carrying out the idea I had long entertained. An opportunity presented itself to me on November 25th. I was doing a vagino-fixation for complete retroflexion.

The patient, twenty-eight years of age, was married nine years, had a child a year later, and a miscarriage at three months, five years ago. Since the miscarriage she has had backache, pain in both groins extending down the thighs, painful menstruation, and a number of other complaints referable to her pelvic lesions. The uterus was in complete retroflexion, both annexa prolapsed, and I was not certain but that I made out some thickening of the distal end of the left tube. After bringing the uterus, or rather the fundus, out at the vaginal wound, I passed a temporary suture through it and gave it to my assistant, asking him to make gentle but steady traction toward the right side. With the index and middle fingers of my left hand I readily delivered the left tube and ovary through the wound. I inspected them carefully, and finding them to be apparently healthy, returned both within the peritoneal cavity. The assistant was then asked to draw the fundus over to the left side, and with the index and middle fingers of my right hand I caught hold of the right annexa, but did not deliver them, which I could easily have done, as they presented nothing abnormal to the touch, and as the room in which I was operating (a tenement-house) was growing very cold. At no time did any bowels come into view, nor did any come into contact with the operator's hands. Vagino-fixation was then done in the usual way, and a Tait's operation for laceration of the perineum. The whole series of operations—1, curettage, 2, inspection and exploration of the annexa, 3, vagino-fixation, 4, Tait's perineum—did not consume more than an hour. The time is mentioned only to show how expeditious the method is, and not as an important consideration. The patient has had absolutely no reaction. Pulse 84, and temperature not going above 99° F. The only complaint made was slight pain in the perineum, from the stitches, for the first few days.

The second case in which I did a vaginal cœliotomy was on November 28th, on an inmate in the Montefiore Home for Chronic Invalids. It was for a complete retroversion and a subperitoneal fibroid the size of a seckel pear, attached to the anterior aspect of the fundus. The patient had entered the Home eighteen months previous for a gastric ulcer, from which she recovered in a short time under proper diet and treatment. But she remained in the Home owing to her inability to work on account of backache, profuse and painful menstruation, and "falling of the womb" (a large rectocele the size of a turkey's egg). The usual longitudinal incision in the anterior vaginal wall for vagino-fixation was made, the vaginal flaps dissected from the bladder, then the bladder was dissected from the uterus, and the vesico-uterine fold of peritoneum cut with scissors. The uterus was next drawn downward and forward by climb-

[1] New York Medical Journal, October 27, 1894.

ing up its anterior wall with three successive provisional sutures. The small fibroid then began to come into view and was easily seized by a volsellum, and taking hold of it with another volsellum, it was readily delivered through the vaginal incision. The capsule was incised and the tumor enucleated from its bed in the fundus, the resulting defect in the uterine wall being whipped over by a continuous catgut suture. The uterus was then vagino-fixated by three silk sutures and the vaginal wound closed in the usual way. The rectocele was next disposed of by an Emmet on the posterior vaginal wall. No reaction whatever as a result of the operation. Temperature only once reached 100° F.; pulse never above 84.

The third case was done at the Post-Graduate Hospital, on December 8th. The patient came from Meriden, Conn., and was referred to me by a former patient. She came to this country from Russia eighteen months ago, her husband having preceded her by three years. Married nine years, three children, last child five years ago. Well until coming to this country, shortly after which began to suffer with metrorrhagia, painful and frequent micturition, backache, pain in the left groin, and pain in various parts of the body. In spite of constant treatment she has been steadily growing worse. Two months ago curetted by the local physician; much worse since then.

On examination she presented the following local conditions: A fairly-sized rectocele and cystocele, an extensive bilateral laceration of the cervix, with considerable hypertrophy of both lips. The body of the uterus was forward, slightly enlarged, and quite sensitive. The left tube at its distal end was the thickness of a lead-pencil, and was adherent to the side of the pelvis. Left ovary small but very sensitive. Right annexa apparently normal. On being told to press down, the rectum became prolapsed for the distance of two inches and presented numerous hæmorrhoidal elevations. Examination of the bladder by Kelly's method showed the interior of the organ to be studded with patches of hyperæmia, and erosions most pronounced at the sphincter vesicæ. Thorough curettage removing considerable granulation tissue. The usual anterior longitudinal incision. Dissection of vaginal flaps from bladder, separation of bladder from uterus. Vesico-uterine fold of perineum torn through with index-finger, fundus brought to the vaginal wound by provisional climbing sutures. With index and middle finger of left hand broke up adhesions holding down tube. Delivered tube through vaginal incision. The fimbriæ distinct and ostium patent. Distal end thickened and congested. Then delivered left ovary in the same manner. It was rather small and showed several small cysts on its surface. These were incised with the scalpel and a clear yellowish fluid escaped. Both tube and ovary then returned within the peritoneal cavity. Right annexa palpated with index and middle fingers of right hand. Nothing abnormal detected, and they were not drawn out. After resecting a strip from either vaginal flap, thus doing an anterior colporrhaphy, vaginal wound sutured in the usual way. Amputation of the cervix. Colpo-perineorrhaphy. Forcible dilatation of rectal sphincter and removal of hæmorrhoids by clamp and cautery. Duration, ninety minutes. Patient next day very comfortable; no reaction. Temperature, 99° F.; pulse, 78. This patient as well as the other two have rapidly convalesced from the operations, without one untoward symptom, and could have been up and about in a week as far as the operation within the peritoneal cavity was concerned.

Quite lately a paper by Dührssen came into my hands, in which he reports a number of cases in which he followed somewhat the same method. He terms it "vaginal cœliotomy," an appropriate term to my mind, and I have adopted it. Dührssen makes a transverse incision in the anterior vaginal fornix and delivers the fundus and annexa through it. I deem the transverse incision, however, less advantageous than the longitudinal. It does not afford so much space, and it does not allow of fixating the uterus in as favorable a position. In a few cases Dührrsen experienced very great difficulty in returning the fundus into the peritoneal cavity. This difficulty does not occur with the longitudinal incision. It offers a further advantage in the feasibility of making a more extensive separation of the bladder from the uterus and broad ligaments.[1] In doing a vagino-fixation on the cadaver, some time ago, and then opening the abdomen, I found that the bladder was completely separated from the uterus and broad ligaments, and was overlying the fundus of the uterus. This free separation of the bladder carries the ureters well forward and removes any risk of including them in any ligature that may be tied.

In my opinion the anterior longitudinal incision possesses many advantages over the transverse incision in the posterior vault for salpingo-opherectomy: 1, There is less hemorrhage, and such as occurs is under better control; 2, it affords more room; 3, there is no danger of cutting into the rectum; 4, there is less likelihood of coming into contact with the intestines in doing the necessary manipulations.

To me there seems to be almost no limit to the amount of work that can be done through the anterior longitudinal incision. If necessary in order to gain more room, the vaginal flaps can also be incised transversely, and the whole hand could readily be introduced into the abdominal cavity. It has also occurred to me how easy it would be to do a hysterectomy in this manner.

In the three cases above narrated it would have been exceedingly easy to ligate the ovarian arteries from above, and the remainder of the operation would have been less than easy. In following the enucleation method, it seems to me, it would also be much simpler and easier to do so from the fundus downward with every tissue in sight, than cutting from below upward in the dark, and not being able to tell when you are cutting into the uterine tissue or keeping outside of it in the so-called vascular sheath. The next opportunity that I have, I intend doing a vaginal hysterectomy by this method.

The importance of being able to substitute vaginal for abdominal cœliotomy cannot be over-estimated. I say this in spite of the fact that I have been exceedingly fortunate in my recent abdominal work. During this year (1894) I have performed 26 abdominal cœliotomies consecutively without a death. These were done for various conditions—large ovarian cancer, 1; ovarian cysts, 3; hysterectomies for fibroid tumors, 2; double pyosalpinx with extensive adhesions, 5; tubo-ovarian abscess, 4; ovarian abscess, 2; salpingo-oöphoritis with adherent retroverted uterus, 5; pyosalpinx unilateralis, 3; appendicitis, 1. They were performed under varying surroundings—Post-Graduate Hospital, St. Elizabeth's Hospital, and Montefiore Home for Chronic Invalids. In many of them the abdominal wound healed by primary union, in others again convalescence was retarded by stitch and mural abscesses of more or less severity. With some exceptions, the patients for the first few days underwent considerable misery from vomiting, thirst, and flatulence. In none has a ventral hernia followed thus far. In two, after a completely smooth convalescence and primary union, small superficial fistulæ, difficult to heal, developed some months afterward, though I used nothing but catgut within the abdomen, and only once a non-absorbable buried suture. I have made it a point to follow up my cases, and I see many a post-operative case in an extensive dispensary practice (embracing over sixteen hundred new cases in a year) that are lost sight of by the operators themselves. I am safe, there-

[1] Dührssen recently reported (Klin. Vort., September, 1894) a case in which, with the transverse incision he accidentally divided the right ureter. Such an accident could not occur with the longitudinal incision.

fore, in saying that my results, immediate and remote, will compare favorably with those obtained by most operators. None of what is gone before is said to disparage abdominal work. Many of the cases operated on could not have been operated on except by the abdominal route, and were saved either from a fatal disease, or one which was rendering life miserable or forming a burden to the victim and her surroundings. The disadvantages mentioned were a mere bagatelle compared with the great gains in life-saving and health that were achieved. Nevertheless, if these disadvantages can be avoided we owe it to the humane office of our calling, and to our patients, to strain every nerve to accomplish that desideratum. I may frankly say that the vaginal route does not make it any easier for the operator. On the contrary, it is a method which makes it harder for the operator, but much easier for the patient.

One has only to compare a few cases treated by the abdominal and vaginal routes, respectively, to be convinced of the truth of this assertion. The advantages of the vaginal route may be stated briefly to be the following :

1. It opens up a smaller avenue for the introduction of deleterious germs. None but the operator's hand need come into contact with the peritoneum and intestines.

2. There is less manipulating of the intestines. In some instances, as in my three cases, they do not come into view, nor in contact with the operator's hands and instruments.

3. The absence of those distressing symptoms, such as thirst, vomiting, flatulence, etc., during the first twenty-four, forty-eight, or seventy-two hours, which may follow the simplest and most skilfully performed abdominal cœliotomy.

4. The avoidance of stitch and mural abscesses.

5. The avoidance of the subsequent occurrence of ventral hernia and troublesome fistulæ.

6. The absence of an external and skin cicatrix. This is more than merely an æsthetic gain. I have seen more than a few patients during the year in whom the cicatrix, though primary union had taken place, gave trouble by being painful, and showing from time to time an angry, red, and swollen appearance.

This is one side of the picture. But the trite saying, " There is nothing perfect under the sun," applies also to the vaginal method. It has its disadvantages. These, however, may be summed up in the one proposition—the greater difficulty of doing the operation—which has already been touched upon. But this, no doubt, will in a great measure be overcome by larger experience and more perfect technique. The danger from meeting with hemorrhage difficult to control is not, in my opinion, very great. This is a point, however, which further experiences will determine.

Another great gain of the vaginal method not yet touched upon is that it opens up a large field for conservative surgery upon the uterus and annexa. The cases of backward displacements, with more or less disease of the annexa, one meets with in public and private practice, form a very large percentage of the cases one is called upon to treat.[1] A conscientious and conservative person hesitates, in many of these cases, to open the abdomen and do what is commonly known as conservative surgery. One weighs the complications which may follow in the trail of a wound through the abdominal parietes. He resorts to curettage, electricity, ichthyol tampons, hot douches, pessaries, etc. He tells his patient she must expect to suffer more or less pain and be content to submit to treatment for a lengthened period, unless she is willing to undergo an abdominal section, which naturally carries with it some dread to the lay mind. Now, if by a method which does not call for an external incision, the backward displacements can be permanently cured, the annexa brought into view and treated upon conservative lines, and with no greater danger or risks, if aseptically done, than attach to a curettage, where is the person who will not urge or avail himself of that method ?

The writer needs scarcely to add that he does not wish to be understood as advising vaginal cœliotomy or vagino-fixation in every case of retroversion of the uterus, and in every case of salpingo-oöphoritis. In many cases the palliative treatment above referred to will prove sufficient. But there will be a fair percentage of cases in which it will fail even after a faithful and intelligent trial. It is in these cases in which palliative treatment has failed that he would urge the method described in this paper. He would also urge it in most of the cases of pyosalpinx and ovarian abscess met with, which have hitherto been treated by abdominal cœliotomy. It would be well, however, until our experience increases and our technique improves, to have our patients and ourselves prepared for an abdominal cœliotomy in the event of our failing to remove the diseased annexa by the vaginal route. The attempt, in the event of failure, would not in the least add to the dangers of the abdominal cœliotomy. Still the writer believes the cases would be few in number in which an operator with any experience in working through the vaginal route would fail.

Note.—Since the foregoing was sent to press I have done vaginal cœliotomy on four further cases. In one case both annexi were removed, as they were hopelessly diseased, the patient leaving the hospital fourteen days afterward. In another case of retroversion with long-continued backache and pain in both groins, the annexi were drawn out through the vaginal incision for inspection. The tubes were found in a fairly good condition, but the ovaries presented a number of cysts, one of which was excised and the remainder punctured. Both annexi were then returned within the peritoneal cavity. Convalescence was perfectly afebrile and satisfactory.

127 East Sixty-first Street.

[1] Of 2,500 cases in my dispensary practice during the past eighteen months, there were 452 cases of retroversions and flexions, the majority of these being complicated with adhesions and disease of the annexa. When we deduct the cases of pregnancies, 295, and the cases which were negative, 210, as far as statistics are concerned, we have a percentage of 22.65 of the total number of cases with pelvic affections.

REPORT OF CASES OF OPIUM-POISONING, SUCCESSFULLY TREATED BY PERMANGANATE OF POTASSIUM.

By WILLIAM MOOR, M.D.,

new york.

In the following I shall give a brief account of some cases of opium-poisoning which were reported to me, one of them having occurred in my own practice.

Case I., reported by Dr. T. S. Buist, of Charleston, professor of surgery in the Medical College of South Carolina.—On February 13, 1894, at 12 M., I was called in haste to see a young woman (white), nineteen years of age, who had taken, by accident, one and a half ounces of laudanum. The poison had been taken at 10 A.M. The first medical aid arrived at about 11 o'clock. Condition upon my arrival : Pupils of both eyes contracted to the finest possible point, eyes dull and glassy, dropping of eyelids ; insensibility to external impressions, pulse slow and intermittent, respiration slow and labored ; almost utter inability to sustain the body upon the limbs. At once a hypodermic injection of one-sixtieth grain of atropine was given, and the result watched with the utmost interest. At the end of thirty minutes all symptoms were aggravated. I ordered as soon as could be procured : Potass. permang. gr. vj. ; Aq. destill. ʒ j. At 12.45 I injected ten drops of this solution in the arm. In ten minutes the patient's locomotion improved. In fifteen minutes she spoke and begged to be allowed to sleep. Pulse

stronger, respiration more regular. Allowed to rest in a chair for five minutes, profound sleep coming on. Patient aroused and ten drops of the permanganate solution introduced in the other arm. The effects in ten minutes were wonderful. Susceptibility of the pupils to light manifest, consciousness returned. Patient in fifteen minutes hysterical and crying; pulse, 76, respiration, 20 per minute. By six o'clock in the evening all symptoms had passed away and a complete recovery was the result.

Case II., reported by Dr. Edwin De Baun, of Passaic, N. J.—On March 3, 1894, at two o'clock in the morning I was awakened by a man who told me he had swallowed seven grains of morphine by mistake for quinine, a half hour before. While relating his experience at first he seemed very lucid, but on further questioning him, his speech became thick and he began to sway from side to side, and implored me to be quick, as the drug was taking rapid effect. I told him to walk about the room, while I went to the inner office and prepared twenty grains of the sulphate of zinc in solution. On returning I found my patient on the floor on his hands and knees trying to keep his head from striking the floor. I raised him, gave him the sulphate of zinc, sat him on a chair and returned to the office for permanganate of potassium. I dissolved ten grains of it in half a glass of water, which only took a few minutes, and when I again returned to my patient, he was lying on his back on the floor, having fallen from the chair where I left him. I administered the permanganate solution, again raised him and placed him upon a chair where I could watch him, while I telephoned for Dr. A. C. Pedrick and sent for two policemen, who took the man into the open air. In the meantime the stomach-pump was made ready. After walking the man a short distance, he went so rapidly under the influence of morphine, that they were obliged to carry him back. We sat him on the back stoop and by this time Dr. Pedrick arrived, and together we tried the time-honored stomach-pump, which of course did not work. We gave him twenty grains more of the sulphate of zinc, which did not act. In a few minutes the man was in a profound stupor, and nothing but the severest handling could arouse him, and then only to elicit a groan, there being no voluntary motions. It was now impossible to administer any medication by the mouth. Therefore we determined to wholly rely on the efficacy of the permanganate of potassium, hypodermically. Three grains were administered by means of a two-drachm aspirator, thinking that the more dilute the solution, the less irritating to the tissues. The first hypodermic was administered one hour and a quarter after the morphine was taken; the second hypodermic in fifteen minutes, and the last hypodermic fifteen minutes later, using in all hypodermically nine grains, which made a total of nineteen grains. It was not until the last hypodermic that he showed signs of voluntary motion, and this was only evinced by raising his leg and scratching it. He soon regained consciousness, and was able to answer questions intelligibly, although when left to himself each time would lapse into a sleeping condition, from which it was difficult to arouse him. He was taken into the house and one-half hour later was able to walk with the assistance of the two policemen. He was now walked to Dr. Pedrick's office, a distance of about five blocks, where he stayed during the remainder of the day, and made a rapid recovery.

The fact that the emetic did not act, and the stomach-pump did not work, and as it was impossible to either walk the man or arouse him by violent manipulations, shows conclusively that the permanganate of potassium must have saved his life.

Before reporting my own case I shall give an account of some animal experiments, the reason for which will be readily understood. As the reader has noticed the permanganate in Case I. was administered only hypodermically. In a private letter which Dr. Buist directed to me he refers to some reports regarding animal experiments I undertook. Those reports were premature, and I must confess I was surprised when I heard of Dr. Buist's case and of other cases in which the antidote apparently was effective even if given hypodermically. Still I remained sceptical and left it to comparative experiments to determine whether or not the much-discussed chemical body had any antidotal virtues with regard to opium if administered hypodermically.

As to those premature reports alluded to, the simple truth about them is as follows: Having found that the antidote would select morphine in the presence of albumin and other organic matter (see Medical Record, February 17th), it came to my mind that this selective power would also manifest itself upon morphine which was held in solution by blood, the latter being principally a solution of albuminous matter in water, and that, therefore, intravenous injections of the antidote might be useful in cases of opium poisoning. In order to substantiate this idea I gave a good-sized rabbit a hypodermic injection of one grain of morph. sulph., followed in fifteen minutes by an intrajugular injection of three-fourths of a grain of potass. permang. (1 to 15), and sixteen minutes after this by another intrajugular injection of one-third of a grain of $Mn_2O_8K_2$. Two hours after the initial injection of morphine, the animal's respiration was 46 per minute, rising to 48 after three hours more.

Another rabbit of the same size also received one grain of morphine but no intrajugular injection of permanganate. Thirty minutes later the animal's respiration was 14 to the minute and one hour after this only 12. Five hours after the injection of morphine the animal still breathed only fourteen times per minute.[1]

To determine the value of hypodermic injections of permanganate in cases of opium-poisoning I used four good-sized rabbits, each weighing about three and one-half pounds (avoirdupois)—1,585 grammes. By giving them hypodermic injections of morphine followed by injections of potassium permanganate, and at a subsequent period only injections of morphine, I was able to draw conclusions as to the value that hypodermic injections of the antidote would have on morphine that was absorbed into the circulation.

Rabbit I.—Received two grains of sulphate of morphine hypodermically at 9.22 A.M., March 1, 1894. Respiration extremely rapid, from fright. At 9.28 I injected four grains of $Mn_2O_8K_2$ in one drachm of water. At 9.32 respiration 120 per minute. At 9.45 the animal is semi-lethargic, but his ears are erect; breathing a great deal slower (50 per minute). After this his breathing gradually improved, being 64 at 10.12, and 60 at 10.22 A.M.; 10.26 A.M., injected two grains of potassium permanganate in one drachm and a half of water; 10.36 A.M., respiration, 76, semi-lethargic, ears erect; 11.15 A.M., respiration, 76; 12.40 P.M., respiration, 153; 1 P.M., respiration, 160; 1.25 P.M., respiration, 150; animal struggling vigorously if held suspended by the ears, general appearance of the animal not lethargic; 2 P.M., power of locomotion begins to return; 2.30 P.M., locomotion much improved; 7 P.M., locomotion entirely restored; 11 P.M. respiration exceedingly rapid, about 200.

March 2d, 8 A.M. The animal drinks water with avidity and takes food; is quite lively; respiration normal (95).

Rabbit I.—Injected two grains of morphine sulphate on March 4th at 1 P.M. At 2.45 P.M., the animal is in a completely lethargic condition; respiration, 26 per minute. At 3.25 P.M., slower, 22; 4.20 P.M., respiration, 21; 5.10 P.M., the same. At 5.50 P.M., the animal is still unable to move voluntarily, but breathes somewhat faster (24). At 7.45 P.M., the power of locomotion begins to return, breathing easier

[1] The normal respiration of rabbits is seventy to ninety per minute. The intravenous injection of the antidote, therefore, was unquestionably of benefit to the animal thus treated.

and quicker, being 70 per minute. At 11 P.M., the breathing is somewhat slower (62).

March 5th, at 8 A.M., the condition of the animal is about normal.

Thus we see that the administration of $Mn_2O_8K_2$ resulted in a decided improvement in the breathing and general condition of the animal. The difference between the results of the two experiments as regards the number of respirations per minute is certainly striking. The heart-action in these two instances and also in the following experiments did not offer any characteristics :

RABBIT II.—Injected on March 2d, at 9.14 A.M., two grains of sulphate of morphia. Respiration, 170; 9.18 A.M., animal is somnolent, lies flat on its abdomen, ears flat on the back ; 9.20 A.M., respiration, 31 ; 10 A.M, respiration, 22 ; the animal is perfectly motionless if suspended by the ears; 10.8 A.M., injected three grains potassium permanganate (1 to 15); 10.16 A.M., injected three grains more of the potassium salt; 10.22 A.M., respiration, 32 ; 11 A.M., somewhat less (30) ; moves about at times; 12.15 P.M., breathing slow (16) ; 12.25 P.M., injected two and a half grains of permanganate ; 12.40 P.M., breathing improved (27); the animal struggles quite vigorously if held by the ears; is much less lethargic ; moves about voluntarily ; 12.50 P.M., respiration, 34 ; 1.20 P.M., animal moves about if put on the floor, power of co-ordination quite fair, tries to escape when approached ; 1.45 P.M., breathing faster (38), regular; 2 P.M., respiration, 45, regular; locomotion normal ; hardly any signs of lethargy ; 9 P.M., respiration, 58, animal is quite lively, drinks some water.

RABBIT II.—Injected on March 6th, at 11.20 A.M., two grains of sulphate of morphia ; 11.50 A.M., the animal is completely lethargic, eyes glassy, breathing slower (38) ; 12.43 P.M., respiration, 22 ; 1.30 P.M., still less (19) ; 4.30 P.M., respiration, 14 ; does not struggle if held by the ears ; 11.30 P.M., locomotion improved. The animal was found dead at 7.30 A.M., March 7th.

RABBIT III.—Injected two grains of sulphate of morphia on March 3d, at 8.20 A.M.; 9.55 A.M., completely lethargic ; respiration, 20 ; 10 A.M., injected four grains $Mn_2O_8K_2$ (1 to 15) ; 10.20 A.M., respiration, 31 ; 10.27 A.M., injected four grains of the potassium salt ; 10.43 A.M., the animal is much less lethargic, moves about voluntarily, struggles vigorously when held by the ears ; 11.13 A.M., respiration, 50 ; 2.30 P.M., much slower (26) ; 3 P.M., injected four grains potassium permanganate ; 3.05 P.M., respiration, 30 ; 5.20 P.M., faster (47) ; 10 P.M., the animal is asleep, but the slightest disturbance will awake it ; held by the ears it struggles vigorously. Locomotion fair, showing perfect co-ordination ; 10.20 P.M., the animal being disturbed ran fast a distance of sixteen feet.

March 4th, 8 A.M., the animal is quite lively and well.

RABBIT III.—Injected two grains of sulphate of morphia on March 6th, at 11.30 A.M. ; 12.30 P.M., respiration, 200 ; 1.35 P.M., respiration, 48 ; 4.35 P.M., respiration, 40 ; lethargic ; 11.30 P.M., the animal breathes fast (90).

March 7th, 8 A.M., the rabbit is drowsy, but breathes very rapidly (130) ; 10 A.M., still drowsy ; 3 P.M., same condition.

March 8th, 8 A.M., respiration labored (84), becoming more and more difficult and slow ; 8.10 A.M., the animal is in extremis, has convulsions, shrieks peculiarly five or six times, dies at 8.15 A.M.

Thus rabbits II. and III. succumbed to two grains of morphine when no permanganate was used to antidote the morphine.

RABBIT IV.—March 8th, 12.30 P.M. Injected three grains of sulphate of morphia ; 12.35 P.M., four grains of potassium permanganate ; 12.40 P.M., respiration, 80 ; 12.55 P.M., respiration, 40 ; 1 P.M., semi-lethargic ; 1.05 P.M., four grains $Mn_2O_8K_2$; 1.16 P.M., respiration, 42 ; 1.40 P.M., respiration, 35 ; locomotion fair ; 2.50 P.M., respiration, 24 ; able to move voluntarily ; 3.05 P.M., four grains potassium permanganate ; 3.20 P.M., respiration, 32 ; 3.40 P.M., respiration, 40 ; 11.20 P.M., respiration, 62 ; the animal is quite lively, locomotion perfect.

March 9th, 8 A.M., the animal is perfectly well ; respiration, 74.

RABBIT IV.—Received an injection of three grains of sulphate of morphia on March 11th at 11.25 A.M. ; 11.40 A.M., completely lethargic ; respiration, 26 ; 1.15 P.M., respiration, 24 ; 4.45 P.M., respiration, 22 ; completely lethargic. At 7 P.M. the condition of the animal is greatly improved.

March 12th, 8 A.M.—Recovery complete.

A comparison of these last two experiments will show that the injections of the antidote were of decided benefit, inasmuch as they were always followed by an improvement in the breathing and the general condition of the rabbit. From an unbiased consideration of the foregoing eight experiments I was justified in concluding that hypodermic injections of potassium permanganate are of great value in opium-poisoning. The question arises, how does the antidote act when thus administered?

When we consider, on one hand, the wonderful affinity of $Mn_2O_8K_2$ for morphia,[1] and, on the other hand, the rapidity of the circulation, it appears quite intelligible that the antidote should select the poison in question from among the albuminous ingredients of the circulating blood, and thus render it harmless. Of course, part of the permanganate will be deoxidized before it can enter the circulation, but evidently enough of it is absorbed to accomplish its wholesome mission.

I shall now return, after this "intermezzo" of animal experiments, to the subject proper of this paper, and shall relate a case of opium-poisoning which occurred in my own practice.

CASE III.—On April 6, 1894, at 8 A.M., I was sent for by Dr. Henry Altschul, of this city, to assist him in a case of morphine-poisoning. On my way to the place I procured one ounce of a 1 to 15 solution of potassium permanganate (gr. xxxij. to ℥ j. aq.). On arriving I found the patient, a young man of twenty-four years of age, in a condition of absolute insensibility, resembling a corpse. His face was livid ; his pupils contracted to the size of a pin's point ; his respiration—four times per minute—spasmodic and stertorous ; his pulse slow, rather full. It was utterly impossible to arouse him or to make him react to any external impression. Dr. Altschul had been with the patient since 7 A.M., resorting to artificial respiration, injections of apomorphine, which produced no emesis, and giving strychnine and atropine hypodermically. As the patient naturally was unable to swallow, I sent to the nearest pharmacy for a medium-sized hard rubber catheter, also a piece of rubber tubing about one-half of a foot long, into which the catheter should fit, and for a glass funnel to fit into the piece of rubber tubing. Meanwhile, in order not to lose time, and having in my mind the results of the animal experiments cited above, I gave the patient a hypodermic injection of 50 minims of the antidotal solution (3⅓ grains of potassium permanganate). This was at 8.30 A.M., half an hour after I was called. At 9 A.M. I administered 15 grammes of the original permanganate solution (16 grains of the antidote), diluted with a cupful of water. This I did by introducing through the patient's nose into his œsophagus the hard rubber catheter, which I had connected with the glass funnel by means of a piece of soft-rubber tubing, and by slowly pouring into the glass funnel the diluted antidotal solution as mentioned above. At 9.30 A.M., the patient's respiration had risen to eight per minute ; but it was still impossible to arouse him. I therefore

[1] See MEDICAL RECORD, February 17, 1894.

gave him another injection of 50 minims of the permanganate solution. A few moments later he gave the first evidence of returning locomotion power by violently tossing with his legs. Soon after this he began to show signs of returning consciousness. At 10.15 A.M. the patient could be made to walk with the assistance of two men. A few minutes later he cried bitterly, embraced and kissed his father, and answered rationally questions that were put to him by those present. Then he asked for black coffee and accepted a cigar, which he smoked vigorously and seemed to enjoy. By questioning him we found out that he had taken, at 6 A.M., one drachm of powdered opium, and for this purpose had filled thirteen gelatine capsules (No. II.) with the opium. We found the empty drachm box at the place indicated by the young man.

About 11 A.M. I gave him seven or eight grains more of the antidote per os, and left him in my colleague's care. The next morning, April 7th, he was practically well and wanted to leave the house in order to make a business call.

Such a quick recovery after such a quantity of poison ingested—sixty grains of opium—and after a fatal issue had seemed almost inevitable is so remarkable that it fully justifies my claim set forth, *that permanganate of potassium is the antidote par excellence for opium.*

CASE IV., occurring in Pittsburg, Pa., reported through the kindness of Dr. Robert P. Finley, of Altoona, Pa.—Patient had taken three ounces of laudanum and was brought to the hospital in a moribund condition, three hours after having taken the poison. No reflex response, respiration four to the minute. As a last resort, after every other means had failed, eighteen and three-quarter grains of potass. permang. were given hypodermically, in the space of two hours and fifty-five minutes. In four hours from the first injection he was perfectly conscious, complaining only of sleepiness.

Up to this date I am cognizant of seventy-one cases of opium-poisoning, in which the therapeutic agent recommended by me as an antidote has been used with unmistakable success, although it is fair to assume that many other cases were not reported.

In the *Canadian Practitioner*, September, 1894, there appeared an able article from the pen of Professor Graham Chambers, of Toronto, in which he comes to the same conclusions I put forward in my original article on the subject. There is only one point on which my opinion differs from that of Professor Chambers. He says $Mn_2O_8K_2$, subcutaneously, is poisonous. Now I have shown in my present paper that rabbits stood hypodermic injections amounting to twelve grains without any deleterious effect, and in the case reported by Dr. R. Finley (Case IV.), the patient had received nearly nineteen grains hypodermically. The mere fact that dogs are susceptible to the action of manganese does not prove that $Mn_2O_8K_2$, given hypodermically in moderate doses to man, would have any toxic effect. Facts point to the contrary. I might state here that Dr. DeBaun's suggestion (see Case II.), to dilute the antidote for hypodermic use as much as possible, is an excellent one; one grain to one drachm of water seems to me a good proportion. Of course, for its use per os, it should be diluted in a much greater proportion, so as to bring in contact with it as much of the walls of the stomach as possible.[1] It might, perhaps, not be unimportant to emphasize once more, in order to avoid mistakes, that permanganate of potassium is not an antidote for all kinds of toxic substances. I have clearly demonstrated that it has absolutely no effect upon atropine,[2] cocain, veratrine, pilocarpine, aconitine, that it could not be depended upon in strychnine-poisoning, in poisoning by oxalic acid and colchicum preparations. I have also shown that even after sixteen hours of contact, phosphorus was not oxidized by potassium permanganate.[1] In connection with this it is highly interesting to know that "peroxide of hydrogen, with all its energetic oxidizing action, has no effect on phosphorus, a substance which is so readily oxidized by the air."[2]

In addition to the foregoing, I found that $Mn_2K_2O_2$ has practically no effect upon muscarine and caffeine, especially in the presence of albuminous matter, and just as little oxidizing power over hydrocyanic acid, although, strange to say, it at once decomposes cyanide of potassium.

In closing this paper, I call the attention of the profession to the fact that opium, its preparations and alkaloids, are our most important and most frequently used remedies. There is scarcely a home, scarcely a family, that does not frequently have within its threshold the great benefactor of suffering humanity—opium—and it is just for this reason that accidents in connection with its general and frequent use are of daily occurrence. I hope, therefore, that the importance of possessing in permanganate of potassium a safe and efficient antidote for opium, its preparations and alkaloids—especially morphine—will not be underestimated.

355 BOULEVARD.

[1] It is now a well-established fact that the mucous membrane of the stomach secretes morphine which had been absorbed into the circulation, and that this secretion continues for many hours.

[2] Including hyoscyamine and hyoscine.

HYDATIDIFORM MOLE.

BY JOHN P. FURNISS, M.D.,

SELMA, ALA.

IN the report of a case of cystic degeneration of the chorion, in MEDICAL RECORD, December 8, 1894, Dr. L. W. Zwisohn states the main points of interest as: 1. Is vomiting one of the main symptoms of hydatid cyst? 2. Do we have positive signs to help in the diagnosis of hydatidiform mole? and what are they? 3. Do they reappear in the same individual, and if so, how frequently? For how long a time is the mole retained in the uterus? 4. Is curetting advisable in cases of hydatid mole? 5. Is it possible that hydatidiform mole should appear independently of conception?

This article, together with a very recent case, recalls my experience with such affections. During the past twenty-seven years that I have practised here (population 7,622), six cases of hydatidiform mole have occurred, three of which were under my immediate charge, and one of which I saw under the care of another physician.

I do not include in this list two cases who gave the history of pregnancy, and had apparently typical abortions which resulted in the expulsion of nothing except a single cyst, like a fish-bladder. In one case the cyst was the size of a walnut, and in the other of a hen's egg.

CASE I.—Mrs. C——, aged twenty-eight, three children, lived on a plantation, but came to town for treatment. She gave the history of four months' pregnancy, nausea, vomiting, etc. Insisted that she felt fœtal movements. Os soft, and cervix shorter than was expected. She had had repeated hemorrhages, which occurred irregularly, generally at night, but never when she was sitting or standing. No cysts discharged. Failing to stop a free hemorrhage with tampon, I introduced and inflated a Barnes bag. The expulsion of a typical hydatidiform mole followed immediately. The mass filled a half-gallon jar, which was kept in my office several years. Convalescence uninterrupted. No recurrence. One child and two abortions since.

Dr. C. J. Clark attended the case with me, and said that it was the first he had seen in a large practice of over forty years.

CASE II.—Mrs. K——, aged thirty-two, five children, consulted me on account of not having felt movements when she had had all the other symptoms of four and

[1] MEDICAL RECORD, February 17th and April 7th.

[2] Dr. L. D. Kastenbine in Louisville Medical Monthly, July, 1894.

a half months' pregnancy. As she was then in good health, she was advised to wait two weeks. She had had no bloody discharges. No cysts passed. Hemorrhage came on suddenly, and on account of my engagements she was attended by the late Dr. C. J. Clark, who told me that the mass which was expelled was similar to Case I. Convalescence prompt and uninterrupted. No recurrence. No children since.

Case III.—Mrs. D——, aged thirty-two, twice married ; two children by each marriage. History of four months' pregnancy, nausea, vomiting, etc., though she was not convinced that she was pregnant. Discharges of colored fluid. Suspected death of fœtus, though uterus continued to enlarge. No cysts passed. Labor pains came on without provocation, followed by profuse hemorrhage and alarming collapse. Uterus emptied manually. Mole same as Case I. Convalescence slow on account of debility. No recurrence. Twins and two other children since.

Case IV.—Mrs. H——, aged twenty-four, primipara, naturally delicate, came from her home in Texas to be nursed by her husband's relatives. She was apprehensive that there was something unusual in her condition, and her husband shared her feeling, especially since the physician who had attended her expressed the opinion that she had extra-uterine pregnancy. History of four months' pregnancy, aggravated nausea and vomiting, fundus above umbilicus, os soft, and cervix obliterated, uterus globular. Taken with elevated temperature, pain in neck and back, excruciating headache, both eyes affected, vision in right limited to counting fingers at two feet distance, urine so albuminous that test-tube could be inverted after boiling without spilling.

Medication failing to produce relief, it was decided, after consultation with Dr. T. G. Howard, to induce abortion. Gum bougie introduced. Two hours afterward regular uterine contractions began and kept up. At the same time a slight flow of blood began and continued until it became necessary to check hemorrhage. At this juncture the diagnosis of probable hydatidiform mole was made. The tampon failing, patient was anæsthetized, the uterus emptied digitally, and then curetted and packed with iodoform gauze. The mass more than filled the top of a slop-jar and resembled boiled sago, the cysts being small and uniform. It was so firmly and universally adherent that it was removed with difficulty and by piece-meal. No further hemorrhage, good reaction, and urine became nearly free of albumin ; but patient died four days afterward from meningitis.

Case V.—Mrs. B—— (under charge of Dr. J. T. West, now dead), aged twenty-two, primapara, history of three months' pregnancy, nausea, vomiting, etc. Treated for abortion. Mass expelled entire. Uterus swabbed with tincture of iodine. No recurrence, and no children, though she has been a widow several years.

Case VI.—Mrs. K——, under charge of Dr. Goldsby King, aged twenty-three, primipara, history of three and a half or four months' pregnancy, intractable vomiting, bloody discharges, no cysts, frequent attacks of pain with symptoms of impending abortion. Was treated for threatened abortion, and no diagnosis of mole was made until after the expulsion of a mass the size of an infant's head. Hemorrhage profuse and collapse protracted. Diarrhœa, fever, and debility interrupted convalescence. After recovery she moved to another place, and her subsequent history was not obtained.

An analysis of these six cases of hydatidiform mole enables me to reply to Dr. Zwisohn's interrogatories as follows :

1. That vomiting is one main symptom of hydatid mole, as well as of the two cases of single cyst reported.

2. That in only one of the cases, was a diagnosis made anterior to the expulsion of the mass, and that diagnosis was only probable. Increase of the uterus to a size greater than that which would naturally correspond to the estimated period of pregnancy, discharge of blood or bloody serum, the escape of vesicles, and the absence of ballottement and fœtal heart-beats and movements, are put down, by such authorities as I have access to, as the characteristic symptoms.

I would like to add three others : Softness of the os, shortening of cervix, and more globular shape of fundus. The sensation of the patient, that there is something unusual or unnatural in her condition, is suspicious and has been a constant subjective symptom in my cases.

3. That there has been no recurrence in the cases reported. That in all of them the mass has been expelled before the fifth month.

4. That curetting is not necessary when the mole comes away entire, and that it is only advisable when it is adherent and has to be removed piecemeal, as in Case IV.

5. That in the light of our knowledge of its etiology it is not possible that hydatidiform mole should appear independently of conception.

The existence of a chorion implies impregnation, and if a hydatid mole is the result of cystic degeneration of the chorion, then conception must have preceded its development. I have never seen an embryo in any of my specimens. Three of the six cases were primipara, and were under twenty-five years of age.

Progress of Medical Science.

Experimental Typhoid Fever. — Dr. Sanarelli publishes a third memoir on this subject, in which he argues strongly that his researches tend to prove that human typhoid fever is not a primarily intestinal affection. (*The British Medical Journal.*) He insists first on the tolerance of the intestinal mucous membrane which may exceptionally be exhibited, especially in the case of relapses, where only the patches which escaped in the first attack suffer. This intestinal tolerance may be obtained experimentally without in any way altering the vulnerability of the organism generally to the virus. A quantity of sterilized culture of Eberth's bacillus, sufficient to vaccinate the animals, was injected by degrees into the stomachs of guinea-pigs, the necessary quantity being determined by simultaneous subcutaneous injection in other animals till these were fully vaccinated. The animals so treated were then inoculated with virus together with others to serve as controls. They died in the same time as these, but exhibited no abdominal symptoms, the meteorism, tenderness, and pain present in the latter being absent. Post mortem, while in the control animals abundant peritoneal exudation was found with typical intestinal lesions, in the others there was no fluid, and the intestines were perfectly normal with their mucous membrane intact. But, at the same time, the other mucous membranes were found congested, which goes to show, according to the author, that the immunity of the intestine results from the habituation of the cells which have eliminated the first poison. A similar immunity was obtained by the injection of putrid beef broth. As in vaccination by subcutaneous injection, the microbes, together with B. coli, tend to disappear from the intestines thus immunized ; but on inoculation B. coli again becomes numerous and virulent, as in ordinary cases, although the intestinal walls have perfect immunity. Investigating the nature of immunity against typhoid, the author criticises and rejects the experiments tending to prove that the serum of immune individuals possesses bactericidal or antitoxic properties. First, as to bacterici-

dal power: Animals vaccinated in the ordinary way were inoculated with virus. The first was killed after two days, and cultures made from the peritoneum were fatal to guinea-pigs in twelve to sixteen hours; cultures from the second, killed after three days, were fatal in ten to twelve hours; cultures from the third, killed after four days, were fatal in eight hours, the usual intestinal lesions following with marked intensity. Therefore, in animals vaccinated against typhoid fever, so far from their serum being bactericidal, Eberth's bacillus flourishes and progressively augments in virulence. Secondly, as to antitoxic properties: Vaccinated animals were found to be even more vulnerable to the toxin than unvaccinated, the hypothermia being more marked and regularly progressive. Further, guinea-pigs and mice were inoculated with toxin mixed with serum of vaccinated animals. With the exception of two mice (notoriously uncertain in reaction), they all died in the ordinary way. On the other hand, the activity of the phagocytes of vaccinated animals is found to be enormously increased. As stated, no peritoneal effusion is found, but the intestines are covered with a thin, sticky layer, which the microscope shows to consist exclusively of leucocytes and endocellular microbes. The author concludes that B. coli and Eberth's bacillus must be considered as distinct varieties. Finally, the author claims that the biological process of human typhoid is to be explained by the knowledge gained by experiment. The earliest symptoms are malaise, fatigue, pains in the head and limbs; the intestinal symptoms only appear when absorption begins. The hyperthermia is a measure of the reaction of the organism to the poison, and if the bacillus of Eberth could fabricate its poison with the same intensity as the cholera vibrio in the human organism, the disease would be rapid and apyretic as in the animals experimented upon.

Anodynes and Hypnotics.—When we consider the number of anodynes and hypnotics that have been introduced within the last few years, and the freedom with which they are now prescribed and administered, it is impossible, according to *The Lancet*, not to be struck with the wealth of means at our disposal for combating the ravages which pain and sleeplessness work on both mind and body. Antipyrin, acetanilide, sulphonal, trional, chloralamide, and others which might be named, will be sufficient to indicate the extent to which our armamentarium has been strengthened. And yet when we think of the powerful effect which those drugs exercise, of the almost immediate relief to most distressing conditions which they so often furnish, it is impossible not to believe that there is "another side to the shield," and that those medicinal agents, blessings in their proper place, not uncommonly become curses and engender a condition of things which is infinitely worse than that to overcome which they were originally administered. When it is a matter of common knowledge that even such a nauseous drug as paraldehyde may actually become the seductive allurement to a harmful habit, it is scarcely to be wondered at if indulgence in other drugs, similar at least in the effects they produce, is occasionally carried to harmful excess. We cannot too strongly deprecate the free and irresponsible manner in which antipyrin, for example, is administered or is taken without medical advice asked or received. One thing in reference to this particular drug is quite certain—and its habitual "eaters" will be the first to acknowledge the fact—and that is that frequent indulgence, as with most drugs, leads to habituation, and that increasingly larger and therefore more harmful doses have to be taken in order to produce the desired effect; and, while the desired effect may be obtained with the larger and more frequent dose, the side effects, so to speak, are also produced more and more strongly, and the patient is in danger of suffering complete physical shipwreck, or at least of producing in himself such a condition of bodily weakness as must render him more liable to succumb to what would be, under other and more favorable circumstances, but a slight illness or a temporary disorder. We do not wish to undervalue this or any other drug of a similar class. Useful and helpful undoubtedly they are, but it should never be forgotten that they are only administered in order, as it were, to mask the painful effects which accompany some departure from physiological health, and that they do not of themselves restore normal function. The sufferer from migraine must not imagine that he is curing his migraine by taking such drugs; he is only saving himself from some of its effects, and unless radical measures are taken to prevent the recurrence of the disorder, he will find that his dose of anodyne has to be repeated more and more frequently, and with increasingly disastrous results to his general health. What has been said about anodynes applies even more strongly to hypnotics. Sleeplessness is no doubt one of the most distressing accompaniments of energy and intellectuality, and however efficacious or apparently harmless certain drugs may be in procuring sleep, such rest is only obtained at some sacrifice and with a certain amount of actual risk. Many of the drugs which are used as hypnotics have been introduced so recently that their full dangers are neither known nor appreciated. Our readers, taking a mental retrospect, will remember how the harmlessness and efficacy of chloral were vaunted, but we now know what danger lurks in its crystals, and what havoc it has wrought and is still working in many lives. Doubtless, artificial sleep has to be obtained sometimes, but it should always be remembered that, in treating sleeplessness with hypnotics, we are only treating a symptom, and that this distressing symptom, unless its cause be rationally combated by other means, will subsequently require stronger, and therefore more harmful, doses of its sedative. The medical profession has great responsibilities in regard to such drugs as we have mentioned, and too great care cannot be exercised in preventing patients from themselves having control of such powerful remedies. They are sadly prone to experiment, not on themselves only, but on their trusting friends, for whom drugs often have the fascination that squibs and crackers have for school-boys; and in more than one instance within our knowledge the chance administration of a drug by one friend to another has had effects so appalling as to be almost incredible.

Toxins and Microbes.—Morny and Marcano conclude, from a series of experiments on the toxin of staphylococcus aureus, that the introduction of a toxin into the body may produce fatal results by causing the escape from the intestine of the microbes present there in a normal state and usually innocuous. Inoculation of antitoxin serum prevented the primary infection, but was powerless to control the secondary. Human pathology offers many instances where a previous infection by a microbe not necessarily dangerous to the host, prepares the way for a secondary infection which otherwise would not have gained a foothold.—*La Médecine Moderne*, December 1, 1894.

Steresol.—This new antiseptic varnish is said to have an advantage over traumaticin, etc., that it adheres to mucous membranes as well as to the skin. It has a bactericidal power equal to pure phenol, but is not caustic. It has been used at the Hôpital Trousseau with eighty-one per cent. of cures in diphtheria. Its value has been demonstrated over a wide range of skin affections, mucous patches, dental caries, lupus ulcers, herpes, pruritus, etc. For surgical use it is painted over the operation wound, site of injury, etc., often with the previous application of iodoform, bismuth subnitrate, salol, etc., in powder; several coats are applied and allowed to dry, and then a light gauze bandage.—*Le Bulletin Médical* December 5, 1894.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, March 2, 1895.

THE DISPENSARY AND HOSPITAL ABUSE.

THERE is no denying the fact that the dispensary abuse has come to be such an outrageous evil, that its continued discussion is constantly crowded upon our attention. In the present issue a correspondent details some results of personal observation which he and every other physician knows is by no means unusual.

It is notoriously true that there is more covert and so-called genteel swindling of professional services in the various dispensaries about town, than in all the other fashionably prevalent endeavors to cheat charity. Nowadays it would seem that a patient who can pay a dollar fee to a young and struggling practitioner, never thinks of going to him, but always hies to the nearest dispensary, where he or she is smilingly welcomed by another professional brother who is always on the look-out for an interesting case. But not only this : It is well known that well-to-do people are constant visitors to the ruinously numerous charity organizations. It is no longer a joke to refer to the sealskins and diamonds on the waiting benches in one of the largest clinics in town. Complaints are of no avail, either to the trustees or the attending staff. Placards are posted to the effect that unworthy persons shall receive no free treatment or advice, but they have no more real effect than if written in an unknown language. Various attempts have been made by different institutions to examine into the circumstances of patients applying for aid, but they have been rendered, in the end, utterly futile, in view of the necessity of a good showing in the annual reports of actual numbers treated, and the consequent claims for increased subscriptions to sweet charity.

One of the main excuses for proper discrimination is the rush of business, that would make the necessary inquiries impossible and impracticable. In most instances it is the organized force in propagating wrong against the ineffectual protest of the individual injured. Even capital appears to be arrayed against legitimate professional labor. Thus we hear of magnificent buildings erected for medical charities, when even the existence of the latter would be absolutely impossible save for the too willingly free services of the profession. The profession has no voice in their management, and no privileges other than to serve the purposes of the managers. This is a trifle humiliating for a learned and honorable profession, but it is, nevertheless, true. There are hundreds of young medical men, even in this city, who are cheated of a legitimate livelihood by the most abominable abuses of these unnecessarily numerous dispensaries and clinics in every available district. The cry that the really poor would suffer for want of free medical attendance, if these so-called charities were decreased in numbers or crippled in opportunities, is absurd. Less than half the number of hospital dispensaries that now exist could well be dispensed with and no really deserving poor patient be neglected.

That the profession itself is to blame for most of these abuses has been so often and so truthfully said, that we are almost ashamed to mention the fact even in a connection that is so legitimately warranted. The only hope is that, in the evolutionary growth of an outraged sentiment, the profession may be forced eventually into some organized and consistent opposition to the powers that be. That this is not very near at hand is quite evident, when we study the complex relations between the aspirations of individuals on the one hand, and the real good of the profession, as a whole, on the other. In a word, the profession is not yet a unit in its own interests. Too often, when the profession is insulted, through one or more of its members, by hospital managers, there is a condoning crowd of eager brethren in line for vacant places. If it were possible for the profession to stand by itself, to demand in a body its rights of hospital managers and dispensary trustees ; to frown down the selfish interests of individuals, and show its real power by organized effort, a proper initiation would be taken to remedy almost every possible abuse of these charities.

The strong and abiding under-current of adverse feeling by the younger members of the profession, so often comes to the surface of discussion, that there is little doubt that some definite and concerted action will yet be determined upon. Already there is a threat to band together and treat the dispensary patients in private offices and private rooms in given districts, and thus retaliate, not only by diverting material from grasping instructors, but by controlling in a certain distributive sense the patronage of a class from which something of an income, small as it may be, may be obtained. The suggestion of our correspondent, that the Charity Organization Society supervise the legitimate claims of the dispensary applicants, is a good one, but it is not at present in the interests of the dispensaries or the medical staffs of the same, in their competition for material, to work in unison with such an idea.

THE HEALTH AND PLUCK OF THE SEVENTH REGIMENT.

THE influence of a high order of intelligence, combined with careful discipline, was very clearly shown by the recent Brooklyn campaign of the Seventh Regiment. Dr. Daniel M. Stimson, the surgeon of the regiment, with no small share of commendable pride, calls attention in his recent report to the remarkable record of ability made by the command to meet an emergency unparalleled in the history of the National Guard. Although composed of men who by social position were unused to any hardships, each and every

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 7, 1895.

JOSEPH D. BRYANT, M.D., PRESIDENT, IN THE CHAIR.

Committee to Raise Library Fund.—DR. REGINALD H. SAYRE, Secretary, said that at the suggestion of the Council he offered a resolution directing the President to appoint a committee, not exceeding twenty-five members, for the purpose of securing the sum of one hundred thousand dollars to place the library upon a solid basis. Adopted.

In accord with a motion to appoint a committee of three on the death of Dr. A. L. Loomis, the President appointed Drs. W. M. Polk, F. Delafield, and A. H. Smith.

Election of Vice-President.—Drs. Ellsworth Eliot and Virgil P. Gibney having declined a nomination, but one nominee remained for the vacancy in the office of Vice-President, and on motion the Secretary was directed to cast an affirmative ballot for Dr. Daniel Lewis. Dr. Lewis was declared Vice-President.

Some Considerations on the Materia Medica and Therapeutics.—DR. E. G. JANEWAY read a paper with this title, prefacing it with the statement that his purpose was to elicit discussion rather than to impress his own ideas. He did not expect unanimity of opinion with regard to the points about to be discussed, especially with regard to what should and what should not be retained in the materia medica.

There were some who believed that all preparations now in the materia medica should be retained, because some might wish to use this, others that kind. The question had frequently come to him as a teacher and student, whether it would not be possible to reduce the number of drugs which it was compulsory to memorize without crippling the beginner's resources in the treatment of disease. Would not such a step be a benefit by allowing the memory to fix itself more advantageously upon the physiological properties and therapeutic indications of drugs instead of upon numerous preparations? Such a plan might be carried out by printing the materia medica for students with the necessary preparations in the text as at present, while less essential preparations were put in parentheses, separated by a line, or placed in the appendix. In this way he thought the unnecessary could be eliminated from the student's crammed mental storehouse.

Here, however, the chief difficulty arose: Who should decide what was necessary and what unnecessary? The teacher would say, teachers of materia medica in the colleges. There was no doubt, Dr. Janeway said, that if each of us were to look conscientiously over the list of drugs which he used, a radical reconstruction of the materia medica on a different basis would result. For instance, since he had left the hospital he had never prescribed assafœtida. He had never seen a case which could not be treated better by other remedies. Sarsaparilla, he thought, was another unnecessary drug. Much of the reputation which both of these enjoyed depended not upon their own activity, but rather upon other ingredients included in the mixture. Among tonics and vegetable bitters the student might be required to learn only the more useful, such as cinchona, gentian, quassia, colombo, and nux vomica. Trouble in making selections might be encountered on such lines as whether willow bark should be included in order to speak of the value of salicin. Dr. Janeway had never used willow bark, but had used salicin. In the class of anthelmintics half a dozen of the drugs in the long list would best answer the purpose of destroying round worms and tape-worms, and the pharmacist would be relieved of the necessity of keeping in stock drugs or preparations which lost their value long before he received any order for their use. Cathartics were also present in large numbers, many of them rarely used, some being retained because they entered into the compound cathartic pill.

Then the synthetic chemists had been at work, trying to produce a panacea of pain, a safe antipyretic, hypnotics, remedies sure to produce red blood-globules and hæmoglobin, non-poisonous antiseptics, etc. If we were to discuss the efficacy of ergot for the control of internal hemorrhage other than uterine, there probably would be a great variety of opinions expressed. This question would have been settled long ago had there been fewer remedies, so-called, of this kind.

The question would be raised as to the method which should be adopted of informing students of all the derivations and antagonisms of remedies. Dr. Janeway would leave that to the professors of materia medica and toxicology. He thought a number of them should be relegated to the supplemental portion. Every combination of iron had been tried, but there was no reason why the student should try to memorize all. Regarding colchicum, of which the materia medica contained numerous preparations, one fluid extract of the seed and root should be sufficient. Another evil was the tendency to recommend some new salt of well-known remedies. This was strikingly illustrated in connection with bromides. The city physician to whom a patient was referred from the country felt that he must prescribe some more efficient preparation than the commonly accepted ones. Much had been claimed for the strontium salts, but they had not come up to expectations. Why should students be obliged to remember all the preparations of opium and rhubarb, and their doses?

Passing to a different phase of his subject, Dr. Janeway mentioned some objections to tablet triturates, which had come to be so generally employed. A chief one was their insolubility. The physician who used large tablets, as of sulphonal and other preparations difficult to dissolve, must not be surprised on getting no effect. In the case of certain tablet triturates, as of corrosive sublimate, he had found patients unable to bear half as large a dose as of a solution of the same drug, the reason being that in the latter form it was distributed over a much larger surface of the stomach.

The author thought medical men did not always appreciate the responsibility which they assumed in endorsing mineral springs or waters which had no special medicinal value. There was no doubt as to the value of some mineral waters when properly used, but it had never seemed to him fair to have patients pay considerable money for something whose only virtue was water.

There was no doubt in his mind that we were led too far in our doing or not doing by the name of the disease. We were inclined, for instance, to treat pneumonia in a certain definite way because it was pneumonia, instead of being governed by the conditions of the case. Incidentally he expressed confidence in having prevented threatened attacks of this disease by diaphoresis, tincture of aconite, and fifteen grains of quinine. Usually, however, too much time had elapsed after the chill before the physician arrived, in order to get the full benefit of this treatment.

It was the first part of his paper which Dr. Janeway wished more particularly to have discussed. Out of the many remedies printed in the materia medica older practitioners had, after hard experience, selected a few; why should medical students be tortured with memorizing all, since most of them would have to be forgotten, the confusion of mind meantime causing indecision in treatment?

DR. WILLIAM H. THOMSON said he had been extremely gratified with the paper. He agreed with the author in the views expressed in nearly every particular. With regard to the excessive number of drugs or

preparations in the materia medica, the most practical comment which he could make was that in his lectures he spoke of one-eighth of those which were officinal, while the other seven-eighths were never mentioned. Of the forty-four preparations of iron he told his students that they would be asked about not more than six. He once illustrated the need of relegating many of the drugs given in the United States Dispensary to a secondary or more distant position by reading with regard to one that it was alleged to have the properties of a tonic, an expectorant, a diaphoretic, an emmenagogue, a deobstruant (he did not know what that meant), and other properties to the total number of fourteen, and what was the remedy? Horehound!

Whatever faults might have been found with his lectures, he supposed one was that he did not speak of all the remedies which students were sure to be asked about on coming up for hospital examinations; but he said he had not found it in his conscience to load their memories with details about drugs which he was sure could be of no service to them in the treatment of the sick.

On the other hand, he was inclined to criticise rather severely the last revision of the Pharmacopœia in greatly changing the strength of well-known preparations and in not sufficiently curtailing the number. In his opinion there should not be a greater number than two or three liquid preparations of opium. The large number at present in the materia medica led to confusion, and was accountable for accidents of poisoning. He cited a personal experience in which the druggist's clerk put up Squibb's preparation of liquor opii compositus instead of camphorated tincture, as his prescription directed. It was with the greatest difficulty that he saved the child.

It was a serious matter to increase the strength of a preparation. Tincture of opium, as prepared now, was twenty-five per cent. stronger than previously; the officinal solution of the sulphate of morphia had been made four times stronger. Magendie's solution here was much stronger than in France, and he knew of instances in hospitals where those who had studied in Paris, forgetting this difference, gave so large a dose hypodermically as to lose their patients. Aconite was one of the best remedies in our materia medica, but only mischief could come from so many preparations. The tincture of the aconite root would save confusion and answer every purpose. There was the extremely dangerous preparation, fluid extract, the physiological dose of which was only half a minim. The present preparation of the solid extract was nine times as strong as the one which preceded it.

Dr. Thomson fully agreed with Dr. Janeway regarding his objections to tablet triturates or pills of any form. If used at all they should be very recently made. Rolling quinine into pills soon caused it to harden. An acquaintance of his who had fever had taken, at successive doses, sixteen quinine pills, and wondered why no effect was produced, until, on going to stool, fourteen were found unaltered. Some tablet preparations were not only insoluble, but they lost their activity. He mentioned nitroglycerine in particular, and said he preferred to administer it in solution.

Regarding the evil of treating diseases instead of patients, it certainly existed to a wide extent. For instance, a man was said to have neurasthenia; how ridiculous to treat such a condition when it was not known what it meant. One said he was treating a patient for anæmia. It would be just as philosophical to say that he was treating him for emaciation. But even greater than the weakness displayed by the profession in treating the names of diseases was that of treating diseases with names. How often did we hear the advice, give him a tonic. Who could define a tonic? The word was from tone in music, but had come to mean anything in medicine which would do the patient good. In a like meaningless way we used the words alterative, nervous sedative, nervous stimulant, etc. There was no general nervous sedative except death; and so-called nervous stimulants increased the function of some portions of the nervous system and depressed others.

Dr. Thomson would like to see a very radical change in our classification of medicines. Two grand divisions recognized by him were: 1, Medicines, one dose of which produced the full effect, or the same effect as subsequent doses—functional medicines; 2, medicines which had to be continued a long time before producing any result, as iodide of potassium given to remove a gumma in syphilis, in which case it did not act as a functional remedy.

The speaker also agreed with Dr. Janeway in his remarks about mineral waters, and said a professional friend once asked him whether he had tried a certain water which the former had found very valuable in Bright's disease. On this recommendation he prescribed it for one of his patients, but she objected to taking it on account of a disagreeable odor. On examination of this specimen, and of another obtained from the proprietors of the water, he found a deposit of all manner of microscopic creatures usually found at the bottom of mudholes.

In conclusion, Dr. Thomson expressed the hope that the paper read by Dr. Janeway would result in the Academy or other medical bodies initiating a movement to eliminate from the materia medica things with which it was entirely useless to burden the memories of already overworked students.

More Corroboratory Testimony.—Dr. George L. Peabody said that as a teacher of materia medica he had come, expecting to be handled by the reader of the paper in a much less gentle manner. As it was, he could corroborate the remarks made, and felt very thankful to Dr. Janeway for the admirable manner in which he had systematized and divided his subject. He agreed with nearly all his propositions. For his own part, he had never been willing to teach students all the different preparations of drugs. He thought it was the function of teachers to lay down certain guiding principles for students which would enable them to judge when certain drugs were called for, and then say to them that these preparations are good and that others are of no account. They should, for instance, learn two or more good preparations of iron, but he would not advise them to learn all the faulty preparations. But there was one thing which had forced him to do more than he would like, namely, the hospital examination bugbear. He had declined to teach the botanical names of plants because he thought it useless, until he was informed that without such knowledge students could not pass an examination to become hospital internes. He was then obliged to say to them that he would give them the botanical name of every plant used in the materia medica; he did not know the names himself, but they might learn them lest they should be asked them by some hospital examiner. It seemed to him that hospital examinations were extremely faulty, especially when conducted by men who were not teachers. Many of the questions propounded seemed intended for the purpose of confounding the student and showing the wisdom of the examiner. Until the hospital examiners should come to be drawn from the ranks of the teachers, the latter would have to teach somewhat wide of the mark. If not, would-be internes would have to go through the treadmill of a cram quiz.

Dr. Peabody thought it was worse than useless to give ergot to arrest cerebral or pulmonary hemorrhage. Most so-called styptics, including tannic acid for intestinal hemorrhage, were useless. Opium preparations were needlessly numerous, and the worst of all was the best known, namely, laudanum. Regarding mineral springs, it was rather painful to him to witness how they were endorsed by doctors. He mentioned

an instance where he was invited to try a certain water, and incidentally to take some stock in the company, and he learned that three members of the Academy had taken some stock, presumably presented to them for booming the water. It was a fact that there was not a single lithia spring which contained enough lithia in any reasonable amount of the water to constitute an appreciable dose. In only one could a person get a moderate dose of carbonate of lithia by drinking a gallon of the water; of the others he would have to drink a barrel.

Regarding faults in the new Pharmacopœia, referred to by Dr. Thomson, he asked if the teachers were not themselves at fault, for they were invited to assist in the revision, and if they had not done so, they were partly to blame. He had seen among country doctors a tendency to use ready-made preparations of all sorts as supplied them by various firms, instead of compounding their own medicines or writing prescriptions. In some of the ready-made pills, tablets, etc., the mixture of the ingredients is very uneven, making them dangerous.

The Other Side.—Dr. Beverley Robinson agreed with most that had been said by the gentlemen who had preceded him, yet there was something to be said on the other side. While there were a good many preparations in the Pharmacopœia which were seldom used by practitioners, some of them entirely useless, yet their presence might help one at times out of some difficulties attending the practice of his profession. For instance, patients with some intelligence were apt to familiarize themselves with ordinary prescriptions, and for one reason or other object to taking them, or perhaps they would have them renewed without instruction. He knew one reputable specialist who overcame this difficulty by writing some hieroglyphic which the druggist understood referred to some prescription left with him. Those long in practice had learned to meet such difficulties; medical students were at a disadvantage after graduation unless taught practical points which could hardly be put into text-books.

Being himself a hospital examiner, Dr. Robinson joined issue with Dr. Peabody in his strictures upon their methods. He was convinced that their object was simply to learn whether those who wished to become internes were able to take care of the patients in the wards, and they asked questions from that point of view. He thought the present time showed too much tendency to the use of alkaloids. It was important that students be taught how to administer drugs in a way to be palatable and agreeable to the stomach. Regarding inertness and insolubility of pills, the doctor should see that his prescriptions went only to druggists who were absolutely reliable, and who never made or sold an insoluble or inert preparation. As to pills, the objections attending them could be avoided by giving powders in capsules. As to mineral waters, he did not base his judgment of their value alone upon their chemical analysis, but also upon the testimony of time.

Dr. Herman M. Biggs said that certainly every teacher of medicine had felt very strongly the difficulties alluded to in connection with the enormous number of drugs, and the enormous number of unnecessary preparations given in the materia medica. He had been in the habit of saying to students, on taking up a certain drug, that there were only a few preparations of it which it was important to remember. But he was in accord with Dr. Peabody, that because of hospital and State examinations they had to give students information which they did not believe would prove of any service to them in practice.

Dr. Biggs thought the error of treating a disease instead of the patient was due to faulty teaching in the schools. The way to correct it was to put general pathology and pathological anatomy on an equal footing with practice of medicine and therapeutics. Until this was done men could hardly be expected to do otherwise than treat names of diseases. One of the hardest things was to get students and doctors to think.

Dr. Biggs said he felt even more strongly than Dr. Janeway had expressed himself with regard to mineral waters. The notion seemed to prevail among laity and profession that there was one spring on the earth intended for the cure of Bright's disease, another for the cure of certain skin affections, and so on. They seemed to think that there was some magical property in the water, whereas its power for good depended solely upon its chemical constituents. In other words, Dr. Biggs did not believe that any mineral-spring water had any influence other than what could be obtained from pure water plus the chemical constituents present in said spring water.

The last statement made by Dr. Biggs led Dr. Robinson to further elucidate his views. Briefly stated, he did not believe chemical analysis would yet enable us to explain the therapeutic value which time had shown was possessed by certain springs.

Dr. Peabody made a few more remarks rather supporting Dr. Biggs.

Dr. Janeway said he had not intended to raise the general question of the value of mineral waters. He believed there had been a great deal of misuse of them.

THE SOCIETY OF MEDICAL JURISPRUDENCE.

Stated Meeting, February 11, 1895.

John S. Smith, President, in the Chair.

Popular Fallacies as to Alcohol and Nicotine.—Albert R. Ledoux, M.S., Ph.D., made this the title of a paper containing the results of his studies as to the injurious ingredients in alcohol and tobacco. He approached the subject from the standpoint of the analytic chemist, rather than that of the moralist, temperance advocate, or advocate of license.

A sign, which read about as follows, seen in nearly all cars, indicated the extent of a fallacy which he wished to combat: "Don't drink. But if you do, drink only the pure article. To be had at ——" The idea conveyed by this and similar advertisements was, that people might drink beer, whiskey, etc., provided the article was pure; they might smoke, provided it was not cigarettes. Those who were accustomed to liquor and tobacco encouraged themselves in the belief that they would suffer no injurious effects, because they used only the products of some reliable manufacturer or some particular brand.

Beers, wines, whiskeys, etc., consisted essentially of water and alcohol, with only two to seven per cent. of other ingredients, unless artificially flavored. The difference between these several beverages consisted almost entirely in the proportion of water to alcohol which they contained. The other constituents were so trifling in amount that we were compelled to accept the statement that there was nothing in them which was injurious unless it was the alcohol. The medical profession and reformers should make the fact clear that if any injury was done it was due to the alcohol; if any benefit was done, it was likewise due to the alcohol, not to the adulteration. After giving the ingredients of different forms of alcoholic beverages, the reader stated the results of an analysis of a number of samples obtained from different saloons in the tenement districts of the city. Where any adulteration was found it related in nearly all cases to the addition of water or water and alcohol. It was very seldom that arsenic, aniline dyes, and other ingredients which might act injuriously were found, and then in such small quantity that no harm could have resulted. In twenty-five samples of brandy no fusel oil was present, and no

coloring matter except caramel. The author did not claim that no injury could come from adulterations, but simply took the ground that, compared with the alcohol, their injurious effects were absolutely insignificant in the quantities found, and this was true even of salicylic acid, which was sometimes added.

Taking up the second division of his paper, the author said that legislation against smoking cigarettes had been to him one of the most interesting phenomena of recent government, especially as he happened to know something of its inception. He was requested by a large dealer in cigars to analyze a number of samples of cigarettes, being told frankly that the sale of cigarettes was so intruding on that of cigars that they wished to lead the public to believe that cigarettes were exceedingly injurious. He undertook the examination as a matter of business, but found no injurious properties not present also in cigars. The cigarette paper contained cellulose, it was true, but not the one-hundredth part as much as was contained in one cigar. It had been asserted that cigarettes contained opium, but he had found none, and the flavoring ingredients used were comparatively harmless. In fact, he found cigarettes adulterated to no greater extent than other forms of tobacco, and any injurious effects which they might exert should be ascribed to nicotine. This was true of tobacco used in any form. But he learned that other chemists had also been set to work, and soon all the newspapers of the country were flooded with matter bearing on the injurious effects of cigarette-smoking, and singular laws were enacted to combat the habit. The form of tobacco most injuriously adulterated was snuff. As prepared for smoking, it could be said that the nearer the article came to being absolutely pure, the higher would be the percentage of nicotine, and there was nothing in the adulterations which approached in potency for mischief nicotine.

In conclusion, let doctors inform their patients in all candor and fearlessness that it was the alcohol and nicotine which they must let alone, and not attempt to shift them from port to sherry, or cigar to pipe, under the vain delusion that they would not be injured.

Dr. T. D. Crothers, of Hartford, was among those who took part in the discussion. He was quite pleased with the scientific character of the paper, and was entirely in accord with the author that the injury done by alcoholic beverages was due to alcohol, and that the injury done by tobacco was due to nicotine. But on the question of the value of alcohol as a nutrient, as a stimulant, as a force-producer, as a medicine, the medical profession was divided. To determine these questions scientifically required close observation and acumen. He had himself been working on the line undertaken by several in Germany and France, of first testing the susceptibility of the different nerve-centres in persons in health, to learn their normal acuteness, and then applying the same tests after the administration of alcoholic beverages. There was general accord in the observation that alcohol diminished the muscular sense, the sense of sight, hearing, temperature, etc. Two ounces of alcohol would produce a very appreciable depression of all the senses, including the intellect.

Dr. Quimby, Dr. Vandenberg, and others made some remarks, some of them wandering from the subject and defending the use of alcohol in medicine and as a beverage, some opposing its use altogether.

The British Orthopædic Society is the name of a new association organized at a meeting held in London on November 3d. Mr. Keetley was elected treasurer, and Messrs. E. Luke Freer, of Birmingham, and A. H. Tubby, of London, secretaries. There is to be no permanent president, each meeting electing its own chairman, as is the rule in the Dermatological and Physiological Societies.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, December 26, 1894.

George C. Freeborn, M.D., President, in the Chair.

Sarcoma of the Heart.—Dr. J. S. Thacher presented the specimen. It had been taken from a man, fifty-nine years of age, whose history revealed nothing bearing upon this condition. Eleven months ago, after some exposure, he began to suffer from dyspnœa, palpitation of the heart, and vertigo. Five months ago he noticed œdema of the feet, which lasted for about one month, and afterward was noticed occasionally to a slight degree. He lost flesh rapidly. Two months ago he came to the hospital. At that time he was emaciated, but not anæmic. An examination of the heart revealed only a moderate roughening of the sounds at the apex. There was some pain in the abdomen, chest, and left shoulder, and later there was severe pain in the epigastrium. About one month ago, grating friction sounds were heard over the apex of the heart, and there were signs of fluid over the left chest. A needle was introduced and clear serum withdrawn, which gave no cultures. The urine showed a trace of albumin, and some granular and hyaline casts.

The temperature was elevated most of the time, ranging between 100° and 103° F. At the autopsy, an abundant fibrinous pericarditis was found, and in the wall of the left auricle a firm mass measuring 3 × 2 × 1½ inches.

It was situated to the back and right of the left auricle, and to the left of the right auricle and superior vena cava. On section it was yellow, gray, and red in patches. Projecting from this into the left auricle was a nodular polypoid mass, measuring 1 × ½ × ⅓ inch. The ventricles were small. There were small vegetations on the mitral and aortic valves, and a slight adhesion of two of the aortic cusps. Each pleura contained above one litre of pure serum. Examination of the stomach showed behind the cardiac orifice a firm mass, three inches in diameter. On section it was cheesy in appearance, and was broken down at the centre, and there was a communication with the stomach by an aperture one inch in diameter. Microscopical examination of these growths showed them to be small, round-cell sarcoma, with considerable hemorrhage and necrosis.

Mycosis Fungoides.—Dr. George P. Biggs exhibited sections of the tumors presented to the Society at its last meeting, as examples of mycosis fungoides. He also reported that the cultures from the meningitis case were pure cultures of the diplococcus lancilatus, and that animals inoculated with these cultures died promptly.

Sarcoma in a Rat.—Dr. Biggs then presented the left anterior extremity of a rat, showing a tumor involving the shoulder and neck. The tumor was well encapsulated, and divided into large lobules. It measured 7 × 4½ × 3½ centimetres. On section, it was for the most part gray, but there were a number of reddish patches, apparently due to hemorrhage. Sections of this tumor were also exhibited under the microscope. They showed it to be a myxo-sarcoma.

The cells of the sarcomatous portion were round cells, small and medium-sized ; a few had two nuclei, but most of them had a single nucleus. The growth was extremely vascular, and through it were scattered areas of hemorrhage. In the same animal, the kidneys showed very marked chronic diffuse nephritis, with the formation of cysts of quite large size. The surface was distinctly granular. The liver contained a small cyst, within which was a worm, 3½ ctm. long, 1 mm. at its small end, and 3 mm. at the larger end.

Anniversary Meeting, January 9, 1895.

GEORGE C. FREEBORN, M.D., PRESIDENT, IN THE CHAIR.

Aortic Aneurism.—DR. GEORGE P. BIGGS presented a specimen of aortic aneurism, which had been removed from a male, forty-three years of age, who had been admitted to the New York Hospital, May 21, 1894. He stated that he had had syphilis when fifteen years of age. He was moderately alcoholic. On admission, he was complaining of cough, and of a pain in the right chest, right arm, and side of the head, which had existed for about one year previously. In the month previous to his admission he had felt something give way while he was putting on his coat, and this had been quickly followed by cyanosis and choking, and by the appearance of a swelling on the side of the neck. Previous to this, some pulsation had been observed in the neck.

Physical examination revealed the following: Diminished voice and breathing at that time over the right chest, both anteriorly and posteriorly; a systolic murmur of low pitch, heard at the apex, and transmitted slightly to the left; in the second left intercostal space there was a systolic murmur, heard over the right border of the sternum, and transmitted upward to the right, and to the vessels of the neck, and heard with maximum intensity in the first right intercostal space. Over the right side of the chest behind, there was a loud, double, blowing murmur, one systolic and the other diastolic. The left radial pulse was slightly stronger than the right. The arteries were slightly tortuous. The liver extended two inches below the free border of the ribs. There was marked œdema of the entire head and neck and upper portion of the thorax; no œdema elsewhere. Over the dull region in the upper part of the chest in front, where the percussion note was dull, there was a distinct pulsation and thrill.

The œdema of the chest increased; he developed œdema of the arms shortly after admission, and later œdema of the abdominal walls and genitals, and fluid appeared in the peritoneal cavity. These symptoms improved after admission, and he was discharged from the hospital; but during the summer he returned on three different occasions, for a few days at a time, because of the dyspnœa. He was last admitted on November 13th, and presented at that time very marked œdema of the neck, head, and upper portion of the chest, the œdema being most marked in the right upper extremity. The face was rather cyanotic, particularly about the ears. He suffered very greatly from dyspnœa, and complained of a constant choking sensation. The cyanosis and œdema increased, and he died on November 30th.
